PREFACE

Here we are on the brink of the twenty-first century. While the history of neurological and psychological research goes back at least two hundred years, the heavy work commenced in the twentieth century. In a hundred short years the basic outlines of the nervous system have been articulated. The biochemical, physiological, pharmacological, and structural features of the vertebrate brain have been described and in many instances defined. So too have the basic perceptual, emotional, mnemonic, attentional, and cognitive functions. In the past 20 years these fundamentals have accelerated at an exponential rate, leaving the field of brain and cognitive science swamped with riches of information.

As we stand poised for the Century of the Brain, never mind the Decade of the Brain, our aspirations have expanded, our know-how has been refined, and our will to tackle the central mysteries of mind/brain relationships has been energized. Five years after the first edition of *The Cognitive Neurosciences* was published, another Summer Institute convened in Squaw Valley to produce its successor: this book. Once again the distinguished section editors led their handpicked colleagues through the maze of new data on the brain and mind. For 18 days, with six lectures a day, the story unfolded. It was a breathtaking experience, and the objective of this book is to bring the benefits of that experience to the world.

For the speakers, it was a chance to meet with friends and colleagues both in their immediate area of expertise and in areas related to the institute's agenda, to trade tales of new developments, and to swat balls around in the California sun. For the fellows and myself, who stayed for the entire three weeks, it was a magnificent smorgasbord, a systematic sampling of a sprawling field.

The forced leisure of being cloistered away from labs, beepers, and coworkers encouraged the fellows' promiscuous attendance at the talks and their exposure to topics and perspectives that otherwise might not have made the cut for their busy schedules. In the words of one, "I never would have sat through all this under any other circumstances." But he was glad he did and, like a lot of others, came away with new perspectives on his own work and new insights into the brain.

This interdisciplinary cross-pollination seems inevitable in a field whose subject is itself both a coherent whole and a motley conglomerate of components. Understanding each nucleus or program of the brain can only be helped by examining the pieces with which it interlocks in this scrupulously well-tuned machine. In fact, this collection demonstrates how many central mysteries of the subject remain outstanding. Despite 40 years of truly impressive elaboration of the molecular biology and cellular effects of the neurotrophins, it is still not known just how these critical chemicals are exchanged between neurons, and why. Four decades after H.M.'s debut, it is not clear whether the hippocampus proper is even necessary for "episodic" memory, whether this form of memory is a truly distinct one, and even, as questioned by an audacious few, whether long-term potentiation is important for memory at all.

The basic functional connectivity that gives rise to the contextual and attentional modulation observed throughout the cortex is almost completely unknown. But the

brain is fixed, and our understanding is expanding exponentially. Powerful technological advances and increasingly sophisticated experimental designs have resulted in an extravagant proliferation of extraordinary discoveries: reach neurons, mirror neurons, rampant attentional effects in V1, linguistic imprinting by absurdly young infants. The behaviorists' oversimplifications and the Freudians' titillated fascinations have been largely tempered with concepts that are necessarily more grounded in experimental fact but which will undoubtedly themselves be eventually transcended. Biology almost defies conceptualization; the limitless complexity of a living system will always outstrip the chunking and abstracting that is our species' peculiar and powerful talent.

The secret of success of this unlikely ape is its ability to stare into a tangle of detail and to see just the things that are most useful, and to use them with its sticky little hands. Any system that can be is simplified, and the ones that can't—if deemed of sufficient importance—are thought about some more until the concepts are close enough to reality for the hands to reach in and pick up a new tool.

An effort this massive is made possible by the hard work of literally hundreds of people. First the section editors and their colleagues devoted dozens of hours if not days and weeks to this project. The beauty of their work is self-evident and tangible as it is represented in this book. Thanks also to the group of outstanding fellows who grilled each speaker with wit and wisdom and also a certain awe. What is not represented is the hard work of dozens of other people behind the scene. These include the indefatigable Darleen Mimaugh and Deborah Holmes of the Dartmouth Continuing Education Program who planned the logistics of the meeting down to the last detail. Thanks also go to Marin Gazzaniga. She has served as the managing editor of this volume and had the horrendous job of not only organizing the 94 chapters in this book but also beating people into making their deadlines. Her constant good cheer, mixed with the occasional look of an assassin, combined with her editorial and managerial talents, made it all possible.

One must also say a word about MIT Press. This organization has continually been there to promote cognitive science and neuroscience, and now cognitive neuroscience. They produce a beautiful product, distribute it around the world, and keep the price as low as possible. Our new editor, Michael Rutter, has been extremely supportive and helpful and has guided this book to fruition.

Needless to say, the field is indebted for the continuing support of the James S. McDonnell Foundation. Starting in 1986, John T. Bruer and his colleague Michael Witunski saw the importance of cognitive neuroscience, and they have been generously supportive ever since. More recently, Susan Fitzpatrick has taken over the management of the cognitive neuroscience effort and in many ways has deepened the Foundation's commitment to this new field. The Foundation has now been joined in its support of the Summer Institutes by the National Institutes of Health and the National Institute of Drug Abuse. Both of these agencies deal with massive problems that will be enlightened by the advancements reported in this book and in the field at large. We thank them all.

Finally, I would like to comment on the thrill and fulfillment I feel in orchestrating this book. I am frequently asked if the task of serving as steward for this enterprise is not overtaxing. The short answer is that it is a huge pleasure, mixed with moments of sheer frustration at having to deal with the details. But all of life is full of boring details. The trick is to have them in the service of something of importance. My hope is that this book will serve as a guidepost for young and old scientists alike for the first years of the twenty-first century.

Introduction

PASKO RAKIC

Developmental neurobiology provides cognitive neuroscience with the rules that govern brain development and set the limits of its capacity for cognition. It also offers clues as to how the brain may have evolved as a biological substrate of cognition. Therefore, this section was designed with the goal of promoting communication between developmental biologists working at the cellular and molecular level in experimental animals and cognitive neuroscientists working on development of behavior in humans.

Five years ago, in the introduction to the Development section of the first edition of *Cognitive Neuroscience*, I expressed my conviction that a badly needed correlation between developmental biology and cognitive sciences would come to pass. Have we narrowed the gap between these two fields of research in the past few years? On the one hand, it could be argued that the gap is actually becoming wider. Developmental neurobiology is becoming more molecular as the use of recombinant technology allows us to study directly the role of individual genes in specific developmental events. We can neutralize selected genes or add new genes, and study the biological consequences. However, the work on the cascades of molecular events and action of various transcription or growth factors is, by necessity, compelling neurobiologists to use simpler organisms, reduced preparations, and in vitro model systems. Moreover, developmental biologists are also concentrating more heavily on early and basic cellular events, such as the determinants of neuronal number through regulation of cell cycle kinetics, programmed cell death, cell lineage pedigree, and the molecular mechanisms of neuronal migration or axonal navigation. They are working less on the challenging, time-consuming task of deciphering the

formation of region-specific synaptic circuitry underlying higher brain function in mammalian brain—particularly in primate cerebral cortex, which resembles the human cortex in the size, complexity, and organization (e.g., see Crick and Jones, 1993; Mountcastle, 1995).

The objectives of cognitive neuroscientists are also changing rapidly. Unlike the past generation of developmental psychologists, many of whom were not really interested in the workings of the “black box,” the present generation is eager to have more information from developmental neuroanatomy and neurophysiology. Such information is critical for the interpretation of sophisticated data obtained from powerful imaging techniques—techniques that were unavailable a scant five years ago. However, the cognitive neuroscientists lack sufficiently detailed and relevant information that is essential or useful for understanding behavior in mammals, and especially primates. Furthermore, the anatomical data are usually not quantitative enough to be useful (e.g., see Crick and Jones, 1993). In the absence of adequate information from neuroanatomy, psychologists are seeking help from modelers, computational neuroscientists, and theorists; or they are moving toward the philosophy (e.g., see Crick and Koch, 1998).

At one level, then, it appears that the gap between developmental biology and cognitive neuroscience has not diminished over the past five years, and may, in fact, be widening. I do not, however, take a pessimistic view. In spite of these trends, I am convinced that we are learning from each other, and that we will come upon empirical generalizations from a common perspective. Furthermore, I believe that the prospect for progress is bright, provided we keep discussing issues of common interest, as has been done at this meeting. A vigorous and continuous exchange of ideas will permit us to elude at least two major sources of impediments: First, that researchers in one field may embrace the data generated from the other without critical evaluation of their significance and real value; second, that simple-minded reductionism may distract researchers from the essential interplay between minute details and the organism as whole—a temptation that arises when the de-

ciphering of narrow issues supersedes functionally meaningful experiments.

Perhaps there are too few “bridge people”—people who can and will synthesize diverse factual information obtained from different levels of analysis (see, for example, Shulman, 1988). Nevertheless, several conceptual issues have been examined and discussed with surprising consensus. The importance of genes and environment cannot and should not be minimized, as both are essential. Without precise genetic programs, we could not develop the extraordinary uniformity evident in the complex system of the human cerebrum. Yet without exposure to sensory stimulation, this system cannot be fully formed. This concept need not be defended today as it was two decades ago (see Goldman and Rakic, 1978). However, it is becoming clear that the environment can only utilize the capacity provided by genes. Similarly, we agree that critical periods in behavior must correspond to specific developmental stages in neuronal differentiation such as the formation of synaptic connections and signaling molecules. Although neuronal activity and functional validation of neuronal circuitry are essential for development of mental skills, synaptic remodeling during development is compatible with selective stabilization among species-specific synaptic patterns that are initially formed by intrinsic genetic information. Finally, there is consensus that our understanding of the causes, pathogenesis, and treatments of mental diseases can be best achieved with full cooperation of the two fields.

1 Setting the Stage for Cognition: Genesis of the Primate Cerebral Cortex

PASKO RAKIC

ABSTRACT Understanding the development of the cerebral cortex is central to our understanding of human intelligence and creativity. Modern developmental neurobiology provides insight into how this complex structure may have evolved, how it develops, and how this finely tuned process may go astray. The initial developmental events, which are the subject of this review, are the production, migration, and appropriate allocation of neurons to their final laminar and areal positions within the developing cortical plate. The genes and morphoregulatory molecules that control these early cellular events are being identified and their functions tested, both in vitro and in vivo, in transgenic animals. The data suggest that the early stages of corticogenesis set the stage for the formation of the final pattern of synaptic connections.

The cerebral cortex in humans makes up about two-thirds of the neuronal mass of the brain and contains almost three-quarters of all our synapses. It is also the structure that most distinctively sets us apart from other species. Therefore, the principles governing the development of the cerebral cortex may hold the key to explaining our cognitive capacity and the evolution of human intelligence and creativity. One of the most prominent features of the cerebral cortex in all species—and particularly in primates—is its parcellation into distinct laminar, radial, and areal domains (Eccles, 1984; Mountcastle, 1995; Goldman-Rakic, 1987, 1988; Rakic and Singer, 1988; Szentagothai, 1987). But although the surface of the neocortex has expanded enormously during phylogeny (e.g., the surface of the human neocortex is 10 times larger than that of a macaque monkey and 1,000 times than that of a rat), its thickness and basic pattern of cytoarchitectonic organization has changed relatively little (Rakic, 1995b).

Understanding the development of the cerebral cortex and its expansion in size and complexity depends critically on answering some fundamental questions: When and where are cortical neurons generated? How is their number regulated in each species and in each individual? What accounts for the expansion of the cortical surface without concomitant increase in thickness?

How do postmitotic cells attain their proper laminar and areal position within the cortex? When and how are different cell phenotypes generated and the regional differences in the cerebral cortex established? Elucidation of these issues is an essential prerequisite for understanding the subsequent formation of neuronal connections and synaptic architecture that underlie our cognitive capacity as well as the pathogenesis of congenital mental disorders.

This account is largely based on studies of neocortical development in the mouse, macaque, and human brain—studies carried out in my laboratory over the past three decades. Although the principles of cortical development are similar in all three of these species, the differences that do exist, however small, offer some very real clues as to how this structure has evolved. The functions of neurotransmitters, receptors, and ion channels do not change substantially over the phylogenetic scale. Thus we can reasonably attribute the secret of *Homo sapiens*' success to an increased number of neurons, more elaborate connections, and functional specialization of cortical areas. In this review, we focus on the early developmental events that lead to the formation of cellular constituents of the cortical plate. Other communications in this volume deal with subsequent formation of neuronal connections and synaptic junctions.

Basic principles

Neurobiologists generally agree that the basic cellular events and main principles of cortical development are similar to those underlying the formation of other parts of the central nervous system (Sidman and Rakic, 1982). Some of these principles and basic developmental events are diagrammatically illustrated in figure 1.1. Initial cellular events (such as the proliferation, migration, aggregation, and death of cells that form the brain), the subsequent outgrowth of axons, and the establishment of neuronal connections proceed in an orderly fashion in each individual according to a species-specific timetable and are regulated by differential gene expression (figure 1.1A, B). In contrast, the later phases

PASKO RAKIC Section of Neurobiology, Yale University School of Medicine, New Haven, Conn.

FIGURE 1.1 The complex organization of the adult central nervous system is the end product of sequential, interdependent cellular events that occur during embryonic development. Starting from the bottom (A) and proceeding to the top of the diagram (D), individual neurons are generated in specific proliferative zones (PZ) and, after last cell division, migrate across the migratory zone (MZ) to attain their final locations. There they form cortical sheets or aggregate into nuclei (C/N). Some cells form transient connections in the waiting zones (WZ) before they enter their appropriate target structures (TS). The final set of neuronal connections,

which are initially more numerous and diffuse, is established by elimination of cells and excess synapses, as shown at the top of the diagram. These basic cellular events can be observed in most regions of the developing brain. As indicated on the right side of the diagram, a major goal of modern developmental neurobiology is to uncover specific genes and molecules that regulate these cellular events in specific structures as well as to understand the mechanisms that enable the environment to influence the formation of neural connections.

of development, including the selective elimination of neurons, axons, and synapses, as well as the shaping of the final circuits within topographical maps, are influenced by activity-dependent mechanisms which—after birth—involve individual experience (figure 1.1C, D). As indicated on the right side of the diagram, analysis of these events can be carried out at the genetic, molecular, and cellular levels. This article focuses exclusively on those aspects of the early events that are represented at the bottom of figure 1.1A and B.

Time and place of neuronal origin

Early studies of neurogenesis found neither dividing nor migrating neurons in the newborn child, suggesting that cortical neurons in human cerebrum must be generated before birth. However, precise data on the onset and termination of corticogenesis could not be established with the available techniques (see Conel, 1939, for example). Use of sensitive and reliable methods to label dividing cells revealed that the neocortical neurons in the

macaque monkey are produced during midgestation (Rakic, 1974, 1988a). In contrast, neurogenesis has been shown to continue after birth both in the cerebellum and the hippocampus (Rakic, 1973; Rakic and Nowakowski, 1981). In the monkey neocortex, however, no additional neurons are added during the animal's 30-year life span (Rakic, 1985). In our own species, comparative cytologic analysis, as well as supravital labeling of dividing neurons in human embryos, indicates that neurons destined for the neocortex are also generated during midgestation (Rakic and Sidman, 1968; Sidman and Rakic, 1973, 1982).

The presence of large numbers of mitotic figures near the lumen of the cerebral cavity of the embryonic human cerebrum and their absence in the cortical plate itself, led to the suggestion that cortical neurons are produced in the germinal matrix situated at the ventricular surface (His, 1904). This hypothesis was substantiated by the application of modern methods for labeling dividing cells in mice (Angevine and Sidman, 1961), monkeys (Rakic, 1974), and humans (Rakic and Sidman, 1968). Proliferative cells in the ventricular zone are organized as a pseudostratified epithelium in which precursor cells divide asynchronously; their nuclei move away from the ventricular surface to replicate their DNA, then move back to the surface to undergo another mitotic cycle (reviewed in Sidman and Rakic, 1973; Rakic, 1988a). Electron microscopic and immunocytochemical analyses revealed the coexistence of neuronal and glial cell lines from the onset of corticogenesis (Levitt, Cooper, and Rakic, 1981; Rakic, 1972). This early divergence of basic cell types has been confirmed using the retroviral gene transfer method, which enables the study of cell lineages in the developing mammalian telencephalon (Luskin, Pearlman, and Sanes, 1988; Cameron and Rakic, 1991).

Transient embryonic zones

During embryonic and fetal development, the telencephalic wall consists of several cellular layers, or zones, that do not exist in the mature brain. Moving outward from the ventricle to the pial surface, these are, in order: the ventricular, subventricular, intermediate and subplate zones; the cortical plate; and the marginal zone (figure 1.2). Although most of these zones were described and characterized in the classical literature at the turn of the century (cf. His, 1904), the subplate zone has been recognized as a separate entity relatively recently (Kostovic and Molliver, 1974; reviewed in Kostovic and Rakic, 1990). This zone consists of early-generated subplate neurons scattered among numerous axons, dendrites, glial fibers, and migrating neurons. Most of these

subplate neurons eventually degenerate, but some persist in the adult cerebrum as a set of interstitial cells (Kostovic and Rakic, 1980; Luskin and Shatz, 1985). Although it has been suggested that the subplate zone provides an opportunity for interactions between incoming afferent fibers and early-generated neurons, the significance of these transient contacts is not fully understood.

One possibility is that the subplate zone serves as a cellular substrate for competition among the initial contingent of cortical afferents and that this competition serves to regulate their distribution to appropriate regions of the overlying cortical plate (Rakic, 1976a, 1977; Kostovic and Rakic, 1984; Shatz, Chun, and Luskin, 1988; McConnell, Ghosh, and Shatz, 1994). Subsequent autoradiographic, electron microscopic, and histochemical studies revealed that the axons observed in the subplate zone originate sequentially from the brainstem, basal forebrain, thalamus, and the ipsi- and contralateral cerebral hemispheres (Kostovic and Rakic, 1990). After a variable and partially overlapping period, these diverse fiber systems enter the cortical plate, and the subplate zone disappears, leaving only a vestige of cells—known as interstitial neurons—scattered throughout the subcortical white matter (Kostovic and Rakic, 1980; Chun and Shatz, 1989). A comparison among various species indicates that the size of this transient zone, as well as its role, increases during mammalian evolution. And this increase culminates in the developing association areas of the human fetal cortex concomitant with the enlargement of the corticocortical fiber systems (Kostovic and Rakic, 1990; Kostovic and Goldman-Rakic, 1983). The regional differences in the size, pattern, and resolution of the subplate zone also correlate with the pattern and elaboration of cerebral convolutions (Goldman-Rakic and Rakic, 1984).

Control of cortical size

The size of the cerebral cortex varies greatly among mammals, reaching a peak surface area in primates. Understanding the principles and mechanisms controlling the production of cells destined for the cerebral cortex may be the key to understanding the evolution of human intelligence. Based on the data on the time of cell origin and cell proliferation kinetics, we proposed that the number of cortical cells depends on the mode of mitotic division (symmetric vs. asymmetric), the duration of the cell cycle, and the degree of programmed cell death in the proliferative zones (Rakic, 1988a, 1995b). In the past few years, technologic advances have allowed us to study the regulation of these cellular events in transgenic mice as well as in nonhuman primates using the retroviral gene transfer method (e.g., Kornack and Rakic, 1995; Kuida et

FIGURE 1.2 Cytological organization of the primate cerebral wall during the first half of gestation. (A) The cerebral vesicle of 60–65-day-old monkey fetuses is still smooth and lacks the characteristic convolutions that will emerge in the second half of gestation. (B) Coronal section across the occipital lobe at the level indicated by a vertical dashed line in A. The lateral cerebral ventricle at this age is still relatively large, and only the incipient calcarine fissure marks the position of the prospective visual cortex. (C) A block of the tissue dissected from the upper bank of the calcarine fissure. At this early stage one can recognize six transient embryonic zones from the ventricular

surface (bottom) to the pial surface (top): ventricular zone (V), subventricular zone (SV), intermediate zone (I), subplate zone (SP), cortical plate (CP), and marginal zone (M). Note the presence of spindle-shaped migrating neurons moving along the elongated radial glial fibers, which span the full thickness of the cerebral wall. The early afferents originating from the brain stem, thalamus, and other cortical areas invade the cerebral wall and accumulate initially in the subplate zone where they make transient synapses before entering the overlying cortical plate. (Reprinted from Rakic, 1995b, by permission.)

al., 1996, 1998; Zhong et al., 1996). Since most genes and their products involved in cell production and fate determination seem to be preserved during evolution, one might expect that the control of neuronal number and differentiation would be basically similar in all species (Williams and Herrup, 1988). For example, one mechanism that regulates the number of cells produced in the ventricular zone is programmed cell death (PCD) or apoptosis. Although PCD has been considered a major factor contributing to the formation of the vertebrate brain (Glucksmann, 1951), contemporary research has focused mainly on the histogenetic cell death involved in the elimination of inappropriate axonal connections in the later stages of development (e.g., Rakic and Riley, 1983a, 1983b; Oppenheim, 1991). However, the discovery of several classes of genes involved in PCD, which were initially identified in invertebrates, afforded the opportunity to study this phenomenon in the mammalian cerebrum. For example, a family of enzymes called caspases has been shown to play an important role in PCD in a variety

of organs and tissues (Ellis and Horwitz, 1991). We have recently demonstrated that in mouse embryos deficient in caspase 9 and 3, fewer cells are eliminated than in their littermates (Kuida et al., 1996, 1998). Reduction of apoptosis in the knockout mice results in the formation of supernumerary founder cells in the cerebral ventricular zone. As a consequence, these mice form ectopic cells in the intermediate zone as well as a larger cortical plate with more radial units. Remarkably, the cerebral cortex in these transgenic mice has a larger surface area and begins to form convolutions. These new approaches provide an example of how the mutation of a few genes that control the reduction of cell death in the proliferative zone could result in the expansion of the cortex during evolution (Rakic, 1995b).

Neuronal cell migration

Since all cortical neurons originate near the ventricular surface of the cerebral vesicle, they must all move to

their final positions in the cortex, which develops in the outer regions of the cerebral wall, just below the pia. Initially, while the cerebral wall is still thin, cells move just a short distance. But the length of their pathway increases with the enlargement of the cerebral hemispheres, particularly in the large primate cerebrum in which a massive migration of neurons occurs concomitantly with the rapid growth of the cerebral wall during midgestation (reviewed in Sidman and Rakic, 1982; Rakic, 1988a). This magnitude of cell movement is perhaps the reason that neuronal cell migration was first observed in human embryos (His, 1874). In the early 1970s, advances in methods yielded the discovery that postmitotic neurons find their way to the cortex by following the elongated shafts of radial glial cells (figure 1.3; Rakic, 1972; Rakic, Stensaas, and Sayre, 1974). These elongated cells, which span the fetal cerebral wall from the beginning of corticogenesis, stop transiently to divide during midgestation at the peak of neuronal migration (Schmechel and Rakic, 1979).

While moving along the glial surface, migrating neurons remain preferentially attached to glial fibers, which suggests a “gliophilic” mode of migration (Rakic, 1985, 1990) that is mediated by heterotypic adhesion molecules (Rakic, Cameron, and Komura, 1994). However, some postmitotic cells do not obey glial constraints and move along tangentially oriented axonal fascicles. (See, for example, the black horizontally oriented cell aligned with TR in figure 1.3.) We suggested the term “neurophilic” to characterize the mode of migration of this cell class (Rakic, 1985, 1990). The lateral dispersion of postmitotic neurons was initially observed in Golgi-stained preparations (see figure 1 of the report of the Boulder Committee, 1970), but it attracted renewed attention after the discovery that a specific, presumably neurophilic, cell class moves from the telencephalon to the olfactory bulb (Menezes and Luskin, 1994; Lois and Alvarez-Buylla, 1994). Moreover, studies in rodents have suggested more widespread dispersion of clonally related cortical cells (reviewed in Rakic, 1995a; Tan et al., 1998; Reid, Liang, and Walsh, 1995). However, we must underscore the fact that application of the same methods in the convoluted primate cortex revealed that the majority of migrating cells obey the radial constraints imposed by the radial glial scaffolding (Kornack and Rakic, 1995; see also the section below: Radial Glial Hypothesis).

Considerable progress has been made in understanding the molecular mechanisms behind neuronal migration and the physical displacement of cell perikarya during translocation of the cell nucleus and soma across the densely packed tissue. Initially, based on an observation *in situ*, it was proposed that a single pair of binding, complementary molecules with gliophilic properties can

account for the recognition of glial guides (Rakic, 1981). In the last decade, however, several candidates for recognition and adhesion molecules have been discovered and are being tested (e.g., Cameron and Rakic, 1994; Anton, Camaron, and Rakic, 1996; Hatten and Mason, 1990; Schachner, Faissner, and Fischer, 1985). It has also been shown that voltage- and ligand-gated ion channels on the leading process and cell soma of migrating neurons regulate the influx of calcium ions into migrating neurons (Komuro and Rakic, 1992, 1993, 1996; Rakic and Komuro, 1995). Calcium fluctuations, in turn, may trigger polymerization of the cytoskeletal and contractile proteins essential for cell motility and translocation of the nucleus and surrounding cytoplasm (Rakic, Knyihar-Csillik, and Csillik, 1996). These studies indicate that neuronal migration is a multifaceted developmental event, involving cell-cell recognition, differential adhesion, transmembrane signaling, and intracytoplasmic structural changes (Rakic, Cameron, and Komura, 1994). A simple model of molecular components involved in cell migration is provided on the diagram in figure 1.4. The discovery of the glial-guided radial migration led to the proposal of the radial unit hypothesis (Rakic, 1988a), which has served as a useful working model for research on the cellular and molecular mechanisms involved in normal and abnormal cortical development.

Radial unit hypothesis

The cellular mechanisms underlying expansion of cerebral cortex during individual development and evolution can be explained in the context of the radial unit hypothesis (Rakic, 1988a, 1995b). The neocortex in all species consists of an array of iterative neuronal groups called, interchangeably, radial columns or modules. These groups share a common intrinsic and extrinsic connectivity and subserve the same function (Mountcastle, 1997; Szentagothai, 1987; Goldman-Rakic, 1987). The larger the cortex in a given species, the larger the number of participating columnar units (Rakic, 1978, 1995b). The radial unit hypothesis of cortical development postulates that the embryonic cortical plate forms from vertically oriented cohorts of neurons generated at the same site in the proliferative ventricular zone of the cerebral vesicle (Rakic, 1978). Each radial unit consists of several clones (polyclones) that migrate to the cortex following glial fascicles spanning the cerebral wall (Rakic, 1988a). In the cortical plate, later-generated cells bypass early-generated ones and settle in an inside-out gradient of neurogenesis (Rakic, 1974). Thus, the two-dimensional positional information of the proliferative units in the ventricular zone is transformed into a three-

FIGURE 1.4 Model of a proposed cascade of cellular and molecular events that take place during the migration of postmitotic cells in the developing cerebral wall. After their last mitotic division in the ventricular zone, migrating cells extend a leading process (LP) that follows the contours of the radial glial fiber (RG) as it spans the expanding cerebral wall. The cytoskeleton within the LP and trailing process (TP) contain microtubules (MT) and actin-like contractile proteins (AC) which are involved in translocation of the cell nucleus (N) and the surrounding cytoplasm within the leading process until the cell enters the cortical plate. This system, maintained *in vitro* in slice preparations or imprint culture, provides an opportunity to examine the role of the various molecules that are engaged in recognition, adhesion, transmembrane signaling, and motility that underlies directed neuronal migration. The voltage-gated (N-type) and ligand-gated (NMDA-type) receptors/channels are thought to control calcium influx, which serves as messengers for execution of this movement. Abbreviations: AM, homotypic adhesion molecule; CT, catenin; EAA, excitatory amino acid; EF, end foot of the radial glial fiber; Gly, glycine; IN, integrin; LP, leading process; MT, microtubule; N, cell nucleus; TP, trailing process; RG, radial glial fiber; RM(g) gliophilic recognition molecule; TP, tyrosine phosphorylation. (Modified from Rakic, 1997.)

dimensional cortical architecture: the x - and y -axes of the cells are provided by their site of origin whereas the z -axis is provided by their time of origin (see figure 1.3).

The radial unit hypothesis accounts for the large expansion of cortical surface that occurred without a concomitant increase in thickness during phylogenetic and ontogenetic development (Rakic, 1988a). It also shows how the genes controlling the number of founder cells at the ventricular surface limit the size of the cortical sur-

face both during individual development and during the evolution of mammalian species (Rakic, 1995b). Thus, a relatively small change in the timing of developmental cellular events could have large functional consequences. For example, a minor increase in the length of the cell cycle or the magnitude of cell death in the ventricular zone could result in a large increase in the number of founder cells that form proliferative units (Rakic, 1988a). Since proliferation in the ventricular zone initially proceeds exponentially owing to the prevalence of symmetric divisions, an additional round of mitotic cycles during this phase doubles the number of founder cells and hence the number of radial columns (figure 1.5; Rakic, 1995b). According to this model, fewer than four extra rounds of symmetric cell division in the ventricular zone before the onset of corticogenesis can account for a tenfold difference in the size of the cortical surface. The mode of cell division changes to predominantly asymmetric after the onset of corticogenesis. That allows us to predict that the extended cell production in humans, which is about two weeks longer than in macaques, should result in an enlargement of the cortical thickness by just 10 to 15%—a prediction that has been observed (Rakic, 1995b). Thus, as illustrated in figure 9.5, even a small delay in the onset of the second phase of corticogenesis results in an order-of-magnitude larger cortical surface owing to the increasing number of founder cells at the ventricular zone.

The proposal that neurons comprising a given radial column may be clonally related could be tested

FIGURE 1.5 (A) Schematic model of symmetric cell divisions, which predominate before the E40. At this early embryonic age, the cerebral wall comprises the ventricular zone (VZ), where all the cells are proliferating, and the marginal zone (M), into which some cells extend radial processes. Symmetric division produces two progenitors (P) during each cycle and causes rapid horizontal lateral spread. (B) Model of asymmetric or stem division, which becomes predominant in the monkey embryo after E40. During each asymmetric division a progenitor (P) produces one postmitotic neuron which leaves the ventricular zone and another progenitor which remains within the proliferative zone and continues to divide. Postmi-

totic neurons migrate rapidly across the intermediate zone (IZ) and become arranged vertically in the cortical plate (CP) in reverse order of their arrival (1, 2, 3, 4). (C) Diagrammatic representation of the time of neuron origin in the macaque monkey. The data were obtained from ^3H -thymidine autoradiographic analyses (Rakic, 1974). (D) Estimate of the time of neuron origin in the human neocortex based on the number of mitotic figures within the ventricular zone, supravital DNA synthesis in slice preparations of fetal tissue, and the presence of migrating neurons in the intermediate zone of the human fetal cerebrum. (Reprinted from Rakic, 1995b, by permission.)

experimentally after the introduction of the retroviral gene transfer method for in vivo analysis of cell lineages in the mammalian brain (Sanes, 1989). Use of this approach suggested that most progenitors originating in the same site of the ventricular zone remain radially deployed in the cortex (Luskin, Pearlman, and

Sanes, 1988; Kornack and Rakic, 1995; Tan et al., 1998; but see Reid, Liang, and Walsh, 1995). Furthermore, a number of studies in chimeric and transgenic mice have provided evidence that a majority of postmitotic, clonally related neurons move and remain radially distributed in the cortex (e.g., Nakatsuji,

Kadokawa, Suemori, 1991; Soriano et al., 1995; reviewed in Rakic, 1995a). The use of the retroviral gene transfer method in the embryonic primate brain showed that even in the large and highly convoluted cerebrum, radial deployment of many clones is remarkably well preserved (Kornack and Rakic, 1995).

Protomap hypothesis

A major challenge to students of the cerebral cortex is how individual and species-specific cytoarchitectonic areas have emerged from the initial, seemingly uniform ventricular zone and cortical plate. Both intrinsic and extrinsic factors have been suggested. One attractive hypothesis is that all cortical neurons are equipotential and that laminar and areal differences are induced by extrinsic influences exerted via thalamic afferents (Creutzfeldt, 1977). However, there is also considerable evidence that the cells generated within the embryonic cerebral wall contain some intrinsic information about their prospective species-specific cortical organization. To reconcile existing experimental and descriptive data, we formulated a protomap hypothesis (Rakic, 1988a). This hypothesis suggests that the basic pattern of cytoarchitectonic areas emerges through synergistic, interdependent interactions between developmental programs intrinsic to cortical neurons and extrinsic signals supplied by specific inputs from subcortical structures. According to this hypothesis, neurons in the embryonic cortical plate—indeed even in the proliferative ventricular zone where they originate—set up a primordial map that preferentially attracts appropriate afferents, and has a capacity to respond to this input in a specific manner. The prefix *proto* was introduced to emphasize the primordial, provisional, and essentially malleable character of the protomap, which is subject to considerable modification by the extrinsic influences exerted at later stages (Rakic, 1988a).

The initial indication that developmental events in the proliferative ventricular zone foreshadow prospective regional differences in the overlying cerebral mantle comes from the observation that the neurogenesis of the primary visual cortex, which contains more neurons per radial unit than the adjacent areas, lasts longer (Rakic, 1976b). Furthermore, it has also been demonstrated that the mitotic index in the ventricular region subjacent to this area is higher than in the adjacent regions (Dehay et al., 1993). Therefore, region-specific differences in production of the ventricular zone can be detected even before neurons arrive at the cortex (Kennedy and Dehay, 1993; Algan and Rakic, 1997). Several lines of evidence indicate that, during the final cell division, one or both daughter cells start to express a variety of neuron class-

specific signaling molecules (LoTurco et al., 1995; Lidow and Rakic, 1994). Postmitotic cells not only become committed to a neuronal fate, but also become restricted in their repertoire of possible fates (McConnell, 1988). There have been numerous studies in which the cytology of postmitotic cells has been examined (e.g., Schwartz, Rakic, and Goldman-Rakic, 1991; LoTurco et al., 1995) and/or manipulated by a variety of methods, including spontaneous mutations (e.g., Caviness and Rakic, 1978; Rakic, 1995b), ionizing radiation (Algan and Rakic, 1997), retroviral gene transfer labeling (Parnavelas et al., 1991), transgenic mice (Kuida et al., 1996), and heterochronic transplantations (McConnell, 1988; McConnell and Kasanowski, 1991). All of these studies indicate that certain cell class-specific attributes are expressed before migrating neurons arrive at the cortical plate and become synaptically connected. In addition, retroviral tracing experiments and some clonal analyses suggest that the ventricular zone comprises a heterogeneous population of cells, and that cell lineage contributes substantially to the cell fate determination of neurons (Aklin and van der Kooy, 1993; Parnavelas et al., 1991; Kornack and Rakic, 1995; Williams and Price, 1995; Kuan et al., 1997).

These findings raise the question of whether laminar and areal identities of cortical plate cells provide cues or chemotactic attractants for incoming afferent axons. Data from axonal tracing indicate that afferent connections from subcortical structures and other cortical regions find their way to the specific regions of the cortical plate either directly and/or via the subplate zone (Kostovic and Rakic, 1984, 1990; DeCarlos and O'Leary, 1992; McConnell, Ghosh, and Shatz, 1994; Agmon et al., 1995; Catalano, Robertson, Killackey, 1996; Richards et al., 1997), suggesting the existence of region-specific attractants for pathfinding and target recognition. In support of this idea, the development of correct topologic connections in anophthalmic mice and in early enucleated animals indicates that basic connections and chemoarchitectonic characteristics can form in the absence of information from the periphery (e.g., Kaiserman-Abramof, Graybiel, and Nauta, 1980; Olivaria and Van Sluyters, 1984; Rakic, 1988a; Kennedy and DeHay, 1993; Kuljis and Rakic, 1990; Rakic and Lidow, 1995; Lidow and Rakic, 1992). Region-specific and morphoregulatory molecules (e.g., Arimatsu et al., 1992; Levitt, Barbe, and Eagleson, 1997; Ferri and Levitt, 1992; Proteus et al., 1991; Buffone et al., 1993; Cohen-Tannoudji, Babinet, and Wassef, 1994; Emerling and Lander, 1994; see also Levitt, chapter 2 of this volume), or layer-specific expression of POU-homeodomain genes (e.g., Frantz et al., 1994; Meissirel et al., 1997) may also contribute to the formation of specified axonal pathways.

Thus, tangentially and radially distinct landmarks in the postmitotic cells facilitate axonal pathfinding and target recognition that eventually lead to parcellation of the cerebral cortex.

It should be underscored that although the embryonic cerebral wall exhibits gradients of several morphoregulatory molecules, as well as other area-specific molecular differences, the protomap within the embryonic cerebrum provides only a set of species-specific genetic instructions and biological constraints. The precise position of interareal borders, the overall size of each cytoarchitectonic area, and the details of their cellular and synaptic characteristics in the adult cerebral cortex are achieved through a cascade of reciprocal interactions between cortical neurons and the cues they receive from afferents arriving from a variety of extracortical sources (Rakic, 1988a). Such afferents may serve to coordinate and adjust the ratio of various cell classes with the subcortical structures, as has been shown in the primary visual system (Meissirel et al., 1997; Rakic et al., 1991; Kennedy and Dehay, 1993; Rakic and Lidow, 1995). In summary, the concept of the cortical protomap includes the role of both intrinsic and extrinsic determinants in shaping the final pattern and relative sizes of the cytoarchitectonic areas.

Timing of cortical genesis in humans

To elucidate the development of the neocortex in humans, it is useful to compare selected cellular features of the human cortex from different prenatal stages with those of the macaque monkey. In so doing, we trace the corresponding times and sequences of developmental events in these species—an essential procedure if we are to apply the findings obtained from experimental animals to the understanding of human cortical development (e.g., Chalupa and Wefers, chapter 3 of this volume). To this end, we make use of Poliakov's comprehensive histologic studies of cortical development in human fetuses, published originally in the Russian literature (e.g., Poliakov, 1959, 1965). These studies have been reviewed in detail elsewhere (Sidman and Rakic, 1982); here, however, these data are summarized in figure 1.6 and compared with the timing of corresponding events in the macaque monkey.

Stage I. Initial formation of the cortical plate (from approximately the 6th to the 10th fetal weeks). During the 7th fetal week, postmitotic cells begin to migrate from the ventricular zone outward to form a new accumulation of cells at the junction of the intermediate and marginal zones. By the middle of this period, synapses of unknown origin are present above and below the cortical plate (Molliver, Kostovic, and Van der Loos, 1973; Zecevic, 1998). This stage corresponds approximately to

the level of cortical development found in the monkey fetus between E40 and E54, depending on the region.

Stage II. Primary condensation of the cortical plate (through approximately the 10th and 11th fetal weeks). At this stage the cortical plate increases in thickness, becomes more compact, and is clearly demarcated from the fiber-rich part of the intermediate zone. This zone seems to have fewer cells per unit volume, indicating that the first major wave of migration is almost spent (figure 1.6). The end of this stage roughly corresponds to the E55-E59 period in the monkey when the majority of efferent neurons of layers 5 and 6 are generated in most regions of the cortex (Sidman and Rakic, 1982; Marin-Padilla, 1988).

Stage III. Bilaminar cortical plate (most pronounced during the 11th to the 13th fetal weeks). The uniform and compact cortical plate of the second stage becomes subdivided into an inner and outer zone: The inner zone is occupied mainly by cells with relatively large, somewhat widely spaced oval nuclei, and the outer zone by cells with densely packed, smaller, bipolar nuclei (figure 1.6). This heterogeneity results from the more advanced maturation of the deep-lying neurons that arrived at the cortical plate during earlier developmental stages, plus the addition of a new wave of somas of immature neurons that take up more superficial positions. This period is also characterized by the appearance of the cell-sparse, fiber-rich subplate zone situated below the cortical plate. This transient embryonic zone in the human fetus is particularly wide in the regions subjacent to the association areas (Kostovic and Rakic, 1990). The third stage corresponds roughly to the level of development achieved in the monkey between E59 and E64.

Stage IV. Secondary condensation (from the 13th to the 15th fetal week). During this period of gestation, the ventricular zone becomes progressively thinner, while the subventricular zone remains relatively wide (figure 1.6). The cortical plate again becomes homogeneous in appearance and resembles, in a sense, a thickened version of stage II. The reason for this change may be that, in stage IV, most of the young neurons in the cortex become considerably larger as they differentiate, while relatively few new immature neurons enter the cortical plate. The result is a more uniform appearance. At the end of this stage, an accumulation of large cells appears below the cortical plate and the subplate zone enlarges further (Kostovic and Rakic, 1990). Depending on the cortical region, this stage appears in the monkey between E64 and E75.

Stage V. Prolonged stage of cortical maturation (from the 16th fetal week continuing well into the postnatal period). Morphological data are inadequate to determine for how long, or how many, neurons continue to migrate

FIGURE 1.3 A three-dimensional illustration of the basic developmental events and types of cell-cell interactions occurring during the early stages of corticogenesis before formation of the final pattern of cortical connections. This cartoon emphasizes radial migration, a predominant mode of neuronal movement which, in primates, underlies the elaborate columnar organization of the neocortex. After their last division, cohorts of migrating neurons (MN) first traverse the intermediate zone (IZ) and then the subplate zone (SP). There they have an opportunity to interact with “waiting” afferents arriving sequentially from the nucleus basalis and monoamine subcortical centers (NB, MA), from the thalamic radiation (TR), and from several ipsilateral and contralateral corticocortical bundles (CC). After the newly generated neurons bypass the earlier generated ones which are situated in the deep cortical layers, they settle at the interface between the developing cortical plate (CP) and the marginal zone (MZ), eventually forming

a radial stack of cells that share a common site of origin but generated at different times. For example, neurons produced between E40 and E100 in radial unit 3 follow the same radial glial fascicle and form ontogenetic column 3. Although some cells, presumably neurophilic in their surface affinities, may detach from the cohort and move laterally, guided by an axonal bundle (cf. the horizontally oriented, black cell leaving radial unit 3 and horizontally oriented fibers), most postmitotic cells are gliophilic; i.e., they have an affinity for the glial surface and strictly obey constraints imposed by transient radial glial scaffolding (RG). This cellular arrangement preserves the relationships between the proliferative mosaic of the ventricular zone (VZ) and the corresponding protomap within the SP and CP, even though the cortical surface in primates shifts considerably during the massive cerebral growth encountered in midgestation (for details, see Rakic, 1988a).

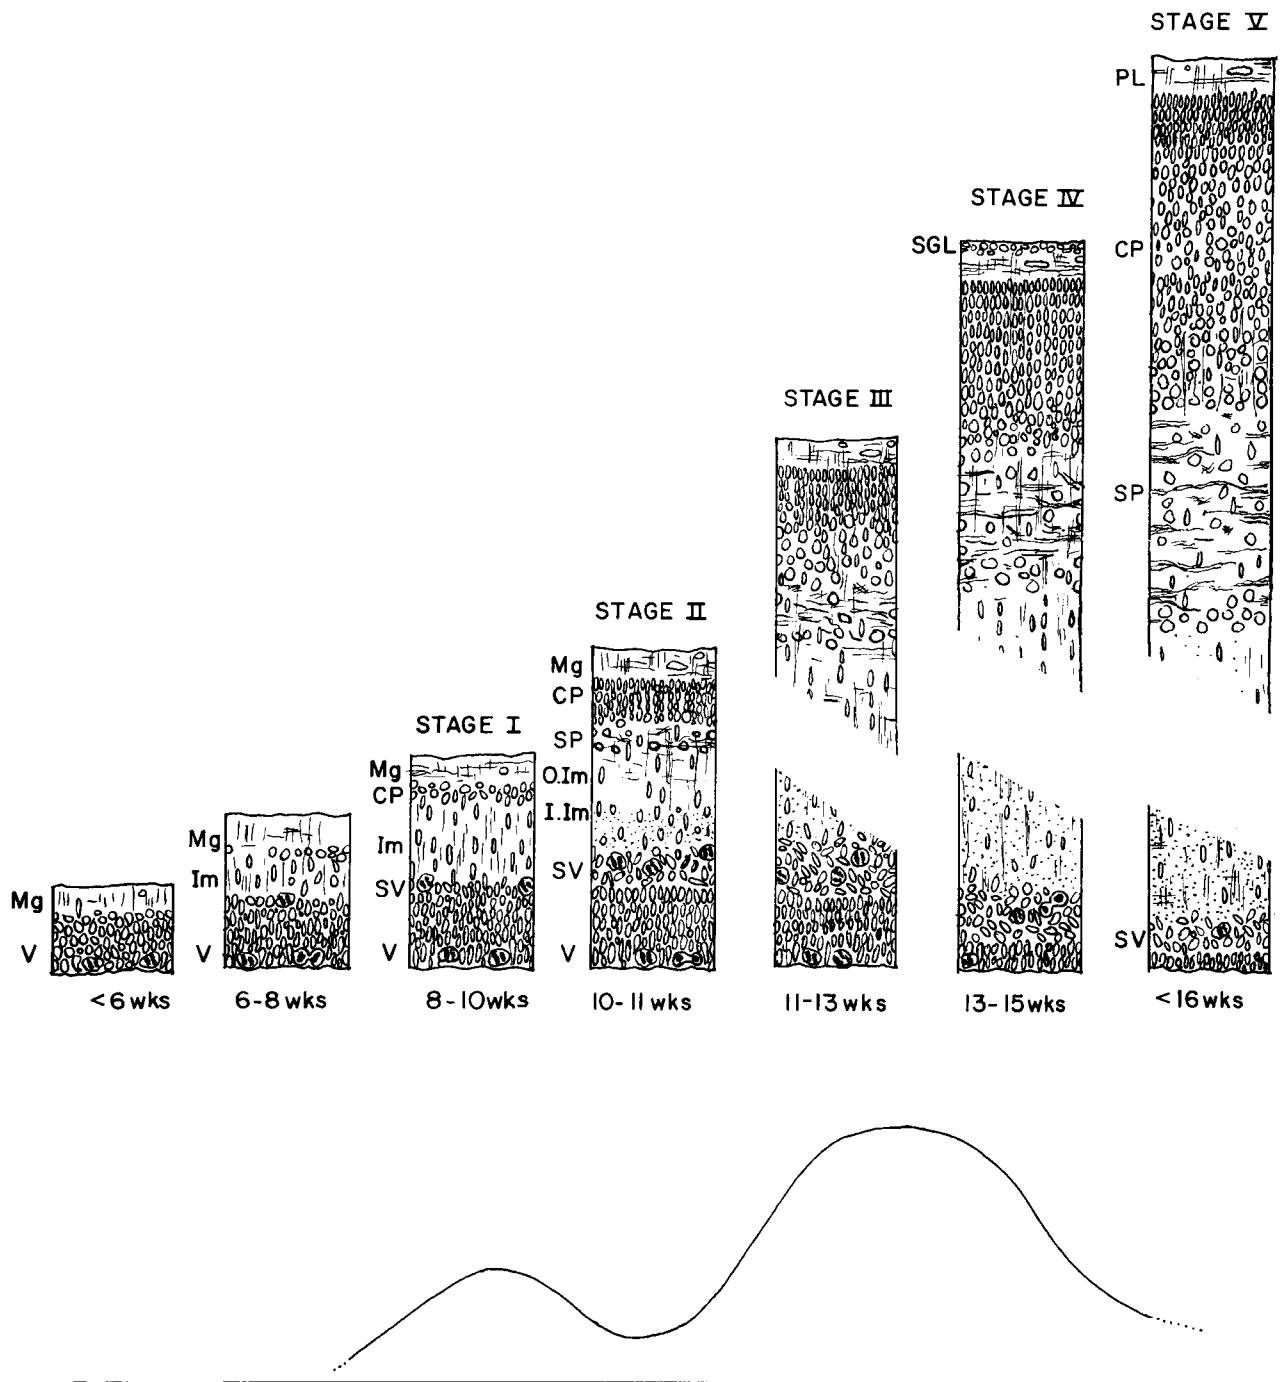

FIGURE 1.6 Semidiagrammatic drawings of the human cerebral wall at various gestational ages listed in fetal weeks below each column. The stages refer specifically to an arbitrarily chosen cortical area situated midway along the lateral surface of the hemisphere (detailed in Sidman and Rakic, 1982). In addition, the subplate zone, situated below the cortical plate, appears in the last three stages (Kostovic and Rakic, 1990). Because there is a gradient of maturation, as many as three of five stages of cortical development may be observed in different regions of the neocortex in the same fetal brain. In the three columns on the right, the intermediate zone is not drawn

in full because the thickness of the cerebral wall has increased markedly compared with earlier stages and cannot fit into the drawing. The curve below the drawing schematically indicates waves of cell migration to the neocortex assessed by the density of migrating neurons in the intermediate zone. Abbreviations: CP, cortical plate; Im, intermediate zone; I.Im and O.Im, inner and outer intermediate zones, respectively; MG, marginal zone; PL, plexiform layer; SGL, subgranular layer; SP, subplate zone; SV, subventricular zone; V, ventricular zone; wks, age in fetal weeks. (Reprinted from Rakic, 1988b.)

to the human neocortex after 16 weeks—hence the dotted line at the right side of the curve in figure 1.6. By the 5th month, relatively few neuronal precursors seem to be proliferating in the reduced ventricular zone of the human cerebral hemispheres, although many neurons generated prior to the 16th week have yet to reach the cortical plate. A comparison of the autoradiographic results in the monkey (Rakic, 1974, 1977) with corresponding stages in human (Rakic and Sidman, 1968; Marin-Padilla, 1988; Kostovic and Rakic, 1990) indicates that most neurons of the human neocortex are generated by the middle of gestation. Toward term, the ventricular zone disappears, the subplate zone dissolves; and, as the intermediate zone transforms into the white matter, only a vestige of the subplate cells remains as interstitial neurons (Kostovic and Rakic, 1980). After all cortical neurons have been generated and attained their final positions, their differentiation, including the formation of synapses, proceeds for a long time, not peaking until the second postnatal year. The subject of synaptogenesis in the cerebral cortex of both monkey and human is described by Bourgeois, Goldman-Rakic, and Rakic in chapter 4 of this volume.

2 Molecular Determinants of Regionalization of the Forebrain and Cerebral Cortex

PAT LEVITT

ABSTRACT Recent advances in molecular and developmental biology have facilitated the discovery of genes and diffusible factors that control regionalization of the central nervous system. The forebrain arises early through a series of inductive interactions between neuroectoderm and underlying mesendoderm—interactions that produce unique gene expression patterns and cytoarchitecture. Environmental challenges to cell fate by transplantation of early embryonic tissues and molecular studies of gene expression patterns also reveal early specification of regions of the cerebral cortex. Early patterning may be responsible for subsequent, restricted expression of axon guidance cues that are necessary for the formation of functional circuits.

Milestone events of cell proliferation, migration, differentiation, and circuit formation underlie the establishment of functional systems in the central nervous system (CNS). A recent explosion of studies has demonstrated that each ontogenetic event is both temporally and spatially regulated by molecular interactions that control the formation of neuronal populations with unique functional properties. In just the four-year period since a related chapter on the topic of cortical regionalization appeared in *Cognitive Neuroscience* (Levitt, 1994), some of the signaling systems that control pattern formation in the CNS have been defined. During early development, a series of morphologic and molecular changes within the forerunner of the CNS, the neural plate, establishes major regions of the neuraxis as the plate rolls up to form a tube. This begins a hierarchical process in which the early neuraxis undergoes regionalization due to anatomically restricted expression of transcription factors and their inducers (Lumsden and Krumlauf, 1996; Rubenstein et al., 1994; Rubenstein et al., 1998; Tanabe and Jessell, 1996). Thus, the differentiation of region-appropriate neuronal phenotypes occurs subsequent to and is dependent upon parcellation of domains in the CNS. The ability of the projection neurons to interconnect within and between

brain regions relies on the further expression of molecules involved in axon guidance (Goodman, 1996; Jessell, 1988; Tessier-Lavigne and Goodman, 1996).

The interactions of diffusible signaling molecules, which arise from nonneural ectoderm and mesendoderm, with neuroectodermal cells begins the complex process of regional specialization that is essential for the subsequent milestone events to take place (Rubenstein and Beachy, 1998). During this process, the basic subdivisions of the neuraxis arise [from rostral to caudal: telencephalon and diencephalon (forebrain), mesencephalon, metencephalon, myelencephalon], with the emergence of dorsoventral and anteroposterior axes. This review focuses on the processes that establish the rostral end of the neural tube, the telencephalon and, in particular, the mechanisms that underlie the regional identity of the cerebral cortex. It is in the context of establishing major brain regions that a framework is built for development of functional specialization in the cortex. Recent research has shown that unique regional properties are expressed early in prenatal development, governed by expression of genes that control neuronal phenotype and the guidance of axon populations to their proper destinations (Levitt, Barbe, and Eagleson, 1997).

Inductive interactions produce the forebrain

Nonneural tissue contributes heavily to the formation of structures that are uniquely found in the forebrain. The notochord, a midline embryonic structure formed during gastrulation, is composed of mesendodermal tissue. Neural-inducing activity has been associated with the notochord; and, in the past decade, studies have shown that a diffusible protein, sonic hedgehog (Shh), is responsible for the initial differentiation of ectoderm into neuroectodermal tissue (Echelard et al., 1993; Tanabe and Jessell, 1996). At the anterior end of the tube, prechordal mesendodermal cells accumulate rostral to the

PAT LEVITT Department of Neurobiology, University of Pittsburgh School of Medicine, Pittsburgh, Pa.

notochord. These cells serve as a source of Shh; and, through activation of the Shh receptor, an initial regionalization of the rostral neural tube occurs. What is accomplished during the early inductive events? Initial differentiation of the neuroectoderm is thought to involve the patterned expression of transcription factors—proteins that bind to specific DNA sequences and thereby control, in a very powerful fashion, the expression of specific genes (figure 2.1). The expression of Shh results in the induction of *Nkx2.1*, a transcription factor found only in the ventral part of the anterior neural tube (Qiu et al., 1998). This region will form the hypothalamus, basal ganglia, and other regions of the basal forebrain. Nonneural ectodermal tissue appears to be required for induction of dorsal structures in the prosencephalon, including the telencephalic vesicles that contain the cerebral wall, the dorsal thalamus, and the epithalamus. It appears that FGF8, a secreted member of the fibroblast growth factor family, is responsible for dorsalization of the anterior neural tube (Rubenstein and Beachy, 1998). The involvement of FGF8 is particularly interesting, because this growth factor is expressed by ectoderm throughout the anteroposterior extent of the neural tube, yet only induces forebrain structures rostrally. In the region of the midbrain, for example, FGF8 induces expression of engrailed 2, a gene that marks the anterior

boundary of the midbrain at the level of the isthmus (Crossley, Martinez, and Martin, 1996). The distinct effects caused by the activation of the same receptor (FGFR) on different populations of cells underscores the critical role of cell location in developmental processes. Thus, cellular context, the spatial and temporal state of any particular cell, has a significant impact on the response of that cell to any particular set of cues that influence differentiation (see Lillien, 1998, for review). When one considers the distinct, local changes induced by FGF8, it is clear that the neuroepithelial cells in the anterior neural tube are distinct from those in the isthmus. Explants of neural plate stage embryos directly demonstrated the different inductive potential of axial mesendoderm (Dale et al., 1997) and differing competence of neural plate cells along the neuraxis (Shimamura and Rubenstein, 1997).

The major dorsal structure of the forebrain, the cerebral cortex, is distinguished from surrounding regions by its laminar appearance, with organized populations of neurons in layers based on their time of origin during fetal development (see Rakic, chapter 1 of this volume). This is in contrast to ventral forebrain structures, which are organized as nuclei or large aggregates of neurons that comprise the basal ganglia, amygdala, and septal region. Studies using explants of early neural tissue have

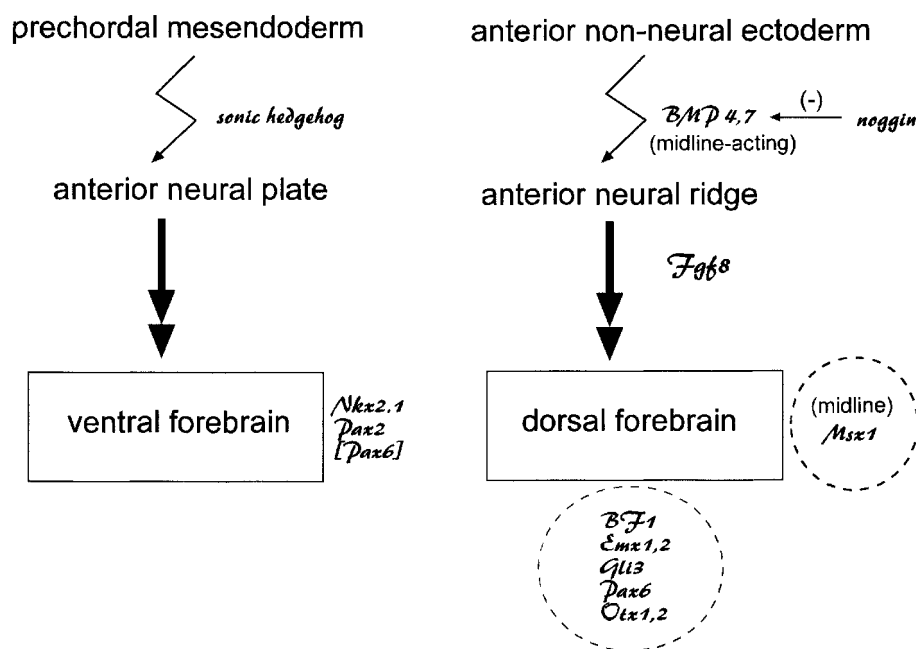

FIGURE 2.1 Schematic diagram illustrating the role of diffusible signals from nonneural tissues in inducing forebrain structures and transcription factors. Prechordal mesoderm is the site of origin of sonic hedgehog, which acts on anterior neural plate tissue to induce ventral forebrain genes such as *Nkx2.1* and *Pax2*. *Pax6* expression is suppressed by sonic hedgehog. Anterior nonneural ectoderm produces bone morphogenetic proteins (BMP) 4 and 7, which act on midline anterior neural

ridge to induce dorsal forebrain marker *Msx1*. Note that *noggin*, which is produced in the forebrain, can act as a negative regulator of BMPs. The anterior neural ridge is the site of *Fgf8* production, which acts on the prosencephalic neural plate to induce dorsal forebrain structures and the subsequent expression of transcription factors *BF1*, *Emx1* and *2*, *Gli3*, *Pax6*, and *Otx1* and *2*.

shown that soon after Nkx2.1 appears in the ventral neuroectodermal cells, Dlx genes are turned on within the same cell populations (Shimamura and Rubenstein, 1997). Dorsally, Bf1, a transcription factor of the winged helix family, is expressed by neuroectodermal cells that give rise to the cerebral hemispheres and dorsal thalamus. These early molecular changes are critical for subsequent specialization of structures because mutations in early ventral or dorsal genes result in severe malformations or even the absence of specific structures (see, for example, Schmahl et al., 1993; Stoykova et al., 1996; Xuan et al., 1995).

Other transcription factors—including members of the *otx* and *emx* family—are expressed in a very rapid fashion just subsequent to Bf1 gene induction. These genes are the vertebrate homologs of *drosophila* genes that are involved in head formation. It has been shown experimentally that isolated anterior neuroectoderm will not develop dorsal structures in the absence of FGF8, suggesting that this molecule may be involved in early telencephalic patterning. Members of the bone morphogenetic protein (BMP) family are expressed in midline neuroectoderm and the anterior neural ridge, the forerunner of the dorsal telencephalon. It has been suggested that both BMP4 and 7 may be involved in dorsal patterning. Mutation of *Bmp4* results in abnormal dorsal midline development (Furuta, Piston, and Hogan, 1997).

Several complicating issues arise in assigning a particular morphologic defect directly to the absence of one specific factor. Many of the genes noted above are expressed in different regions of the early neural tube and participate in multiple inductive events. The hierarchical nature of the molecular interactions is likely to result in complex changes when one gene is mutated. For example, mutations of *Otx* genes result in the anterior movement of FGF8 expression and the posteriorization of the neural tube (Acampora et al., 1997; Suda et al., 1996). In addition, growth factors have pleiotrophic effects (reviewed in Lillien, 1998). Thus, a molecule may be mitogenic for one particular cell population, but cause phenotypic differentiation of that same cell population at a later time [see the example of epidermal growth factor (EGF) below]. Such multiple activities complicate the interpretation of defects that arise from the deletion of any one particular gene.

Regionalization of the cerebral cortex

Progress in understanding the molecular and subsequent anatomic specification of the neuraxis has been both rapid and dramatic in the past few years. But that progress has been, and remains, difficult. What, then, has

been the difficulty in determining the extent to which different functional domains of the cerebral cortex are determined prior to experiencing subcortical influences? In fact, studies examining the basic patterning of the neural tube employ an experimental design that relies on the ability to assay specific features, or phenotypes, of the tissue in order to evaluate the extent to which cells in that region express unique features. At a rather global level, one focuses particularly on those characteristics that distinguish regions of the CNS, which themselves may contain heterogeneous nuclei and laminated structures. In the cortex, it is somewhat enigmatic that the establishment of unique cortical cytoarchitectonics, by similar populations of neuronal subclasses [glutamatergic projection and GABAergic interneurons, at a consistent ratio of approximately 6:1 (Beaulieu, 1993; Hendry et al., 1987)], occurs rather late in development, well after connections from the thalamus are established. We have hypothesized that the early decisions made by cortical progenitors to differentiate into specific types of projection neurons provide the framework upon which unique functional areas and their associated connections form. This hypothesis is based on data demonstrating that projections from thalamus to cortex (and those reciprocal connections) form without errors in a very specific fashion (Agmon et al., 1995; DeCarlos and O'Leary, 1992; Erzurumlu and Jhaveri, 1992; Miller, Chou, and Finlay, 1993). The specific targeting suggests that there are molecular differences (both positive and repulsive cues) in the cerebral wall that guide axons to their appropriate functional area. While the molecular mechanisms that control the decisions pertaining to cell fate in different cortical regions are beginning to be understood, recent studies using experimental manipulations of the environment in which cells develop indicate that cortical regionalization may be a complex process.

The cellular environment influences phenotypic potential

Experimental embryologists have utilized a time-honored method to approach the question of how the potential of a cell or tissue to differentiate and express particular phenotypic characteristics is established. One can test the differentiative potential of a piece of tissue or individual cells by placing them into an environment that they normally do not experience (heterotopic). This type of experimental approach is particularly useful when the novel environment is sufficiently different from the normal (homotopic) location of the tissue or cells that are harvested for transplantation. The timing of the manipulation is critical: Grafting the tissue or cells prior to expression of the particular phenotype

tests the ability of the tissue or cells to express the feature in a foreign environment, while moving the tissue after expression tests the ability of the tissue to maintain the phenotypic feature in a different environment. This experimental strategy has been used at the cellular and tissue levels with cortical material, and some common mechanisms of development have emerged (Levitt, 1994; Levitt, Barbe, and Eagleson, 1997). Progenitor cells by definition are mitotically active and have not yet differentiated into postmitotic neurons. Progenitors appear to have the greatest potential to develop into a variety of neural cell types. For example, forebrain progenitors will integrate into heterotopic sites of the telencephalon, brainstem, and cerebellum and differentiate into neurons appropriate for each site (Brustle, Maskos, and McKay, 1995; Campbell, Olsson, and Bjorklund, 1995; Fishell, 1995). The neurons even form correct connections. Within the forebrain, progenitors have the capacity to respond to novel environmental cues that alter their predicted cell fate. Laminar position in the cerebral cortex is a predictor of particular neuronal phenotypes because cells in different layers project to different targets. Progenitors obtained at a time when deep-layer neurons are produced can be transplanted to older host brains and will migrate to superficial layers, like their host counterparts, even making connections specific for superficial neurons (McConnell and Kaznowski, 1991). The complementary experiment, in which progenitor cells from older fetal brains are harvested and transplanted into younger hosts, failed to generate the same result (Frantz and McConnell, 1996). The older progenitor cells produced neurons that migrated to more middle and superficial layers. These data suggest that even progenitors can change with time, becoming more restricted in terms of what they can become. This restriction may be due in part to altered expression of growth factor receptors that make a cell more or less responsive to a particular environmental cue (Burrows et al., 1997; Lillien, 1995; Lillien, 1998).

Experiments focusing on regional properties of cortical tissue have been done in parallel with those examining individual cellular characteristics. In the late 1980s, transplantation of small pieces of fetal tissue was performed between occipital (visual) and dorsal frontoparietal (sensorimotor) cortex. When descending projection patterns of the transplanted neurons were analyzed, it was found that even transplants of late fetal tissue could alter their "normal" normal projections and, instead, develop efferents to brain regions most appropriate for their new location (O'Leary and Stanfield, 1986). The number of neurons that exhibited this capacity was not known at the time; however, recent

quantitative studies using a similar transplant strategy have shown that the majority of neurons project subcortically in a manner reflecting their origin rather than their new environment (Castro et al., 1991; Ebrahimi-Gaillard and Roger, 1996; Garnier, Arnault, and Roger, 1997; Garnier et al., 1997). It is therefore likely that, for some projection patterns, many postmitotic neurons can maintain features characteristic of their donor location, the area in which they initially differentiated. This implies that younger transplants, containing more progenitor cells, would exhibit more plasticity. Does this make sense functionally? It is reasonable to predict deficits in functional recovery with transplanted tissue that exhibits mostly aberrant projections based on a new location. Indeed, recent studies have shown that late fetal tissue harvested from occipital cortex cannot subserve functional recovery of somatosensory tissue that it replaced in host animals (Barth and Stanfield, 1994).

Studies in which molecular markers have been used to monitor differentiation of cortical tissue have led to similar conclusions. The expression of the limbic system-associated membrane protein (LAMP), a cell adhesion molecule involved in the development of limbic circuitry (Keller et al., 1989; Levitt, 1984; Pimenta et al., 1995; Zacco et al., 1990), is restricted in the cortex to limbic regions such as medial prefrontal, anterior cingulate, and perirhinal areas (Ferri and Levitt, 1993; Horton and Levitt, 1988; Pimenta, Reinoso, and Levitt, 1996; Reinoso, Pimenta, and Levitt, 1996). Progenitor cells from neocortical regions can express LAMP when placed into a neonatal host environment in which neurons normally express the protein. The change in cell fate of neocortical progenitors is more pronounced when harvested from very young (E12-14) fetal tissue, a time when neuron production is just beginning (Barbe and Levitt, 1991). Perhaps the most striking outcome of these transplant studies was the finding that changes in molecular expression of LAMP by the tissue was paralleled by predictable patterns of thalamocortical and corticocortical projections (Barbe and Levitt, 1992; Barbe and Levitt, 1995). Thus, grafts that contained substantial numbers of LAMP⁺ neurons also exhibited limbic thalamic and corticocortical connections. LAMP⁻ grafts of somatosensory tissue formed primary sensory neocortical and thalamic connections in the host (Barbe and Levitt, 1992, 1995). Other, subsequent, studies used different molecular markers to document a link between specification of cell populations destined for certain domains of the cerebral cortex and proliferative potential of the cells (Arimatsu et al., 1992, 1994; Cohen-Tannoudji, Babinet, and Wassef, 1994; Soriano et al., 1995).

Cellular dispersion and cortical specification

The radial deployment of cells from the ventricular zone, where neuronal birth occurs, to a final location in the cortical plate is central to the protomap concept, in which the general position of the cell in the neuroepithelium defines the areal destiny of the neuron (Rakic, 1988). This has important implications for the mechanisms that ultimately control the formation of functional circuits involving the cerebral cortex. The concept has been challenged recently, primarily because of studies that document cell dispersion across the cerebral cortex. Retroviral lineage tracing with complex virus libraries has shown that clonally related cells, arising from individual progenitors, can be dispersed to distant locations in the mature cerebral cortex (Walsh and Cepko, 1992). Coupled with this finding, videomicroscopy has shown that one-quarter to one-third of the cells labeled in the ventricular zone of the cerebral wall will move nonradially to the cortical plate, dispersing to locations distant from the radial domain (O'Rourke et al., 1992, 1995). This is not the case for very early progenitors, prior to cortical plate formation; similar labeling studies in explants show that progenitor cells disperse, either by active migration or nuclear translocation, to overlying radial locations (O'Leary, personal communication). Recently, a third piece of evidence suggested that tangential dispersion of subpopulations of neurons is likely to occur in cortical development (Anderson et al., 1998). The fate of progenitor cells in the subventricular zone of the lateral ganglionic eminence (LGE), the region traditionally thought to give rise solely to basal ganglia structures, was monitored in explants of the forebrain from normal and *Dlx-1/Dlx-2* mutant mice. In normal mice, GABAergic neurons from the LGE migrate across the pallido-cortical boundary into the cerebral wall to seed widespread cortical areas with interneurons. This fails to occur in the *Dlx* double knockout mice. Using chimeric animals in which an X-inactivated transgene marks cortical columns (Tan and Breen, 1993; Tan et al., 1995), Tan et al. (1998) showed that glutaminergic (projection) neurons settle in strictly radial patterns, whereas GABAergic interneurons disperse relatively randomly, both within and outside marked columns in the neocortex. These data suggest that cellular dispersion in the cerebral cortex may be more precisely controlled than originally thought, with neurons responsible for establishing area-specific subcortical and corticocortical projections migrating radially from defined regions of the ventricular zone, consistent with the protomap hypothesis (Rakic, 1988).

The dispersion of neurons in the cerebral wall appears to take place in different zones. The lineage studies

showed that many retrovirally labeled progenitors moved tangentially within the ventricular zone (Walsh and Cepko, 1993). We suggested that this movement would result in respecification of progenitors that reside in a new microenvironment, prior to exiting the cell cycle (Ferri and Levitt, 1995). This hypothesis is consistent with transplant studies showing that the phenotypic fate of mitotically active cells can be altered in different environments (Barbe and Levitt, 1991; Brustle, Maskos, and McKay, 1995; McConnell and Kaznowski, 1991; reviewed in Levitt, Barbe, and Eagleson, 1997). The specific phenotypes of the cells that migrate tangentially within the fiber-rich intermediate zone may be complex and could include interneurons and nonneuronal cells. The findings do suggest that not all postmitotic neurons exhibit immutable area fates and hence that cells can be influenced to express particular area-specific features later in development. We do not know, as yet, the signals that guide these choices made by neurons in late gestation. In fact, only recently has the use of model culture systems helped dissect mechanisms that control early events of cellular differentiation.

Molecular basis of cortical regionalization

Different molecular, structural, and organizational features of a neuron help define its particular phenotype. The analysis of signals that control cell fate choices is beginning to reveal that different phenotypic characteristics may be regulated by fundamentally different mechanisms. Why is this an important issue for understanding cortical development? As noted above, we have suggested that the early decisions made by cortical progenitors to differentiate into specific types of neurons provide the framework upon which unique functional areas and associated connections form. Transplant studies support this idea (Barbe and Levitt, 1992, 1995; Barth and Stanfield, 1994; Ebrahimi-Gailard and Roger, 1996; Garnier, Arnault, and Roger, 1997; Garnier et al., 1997). As in *drosophila* and vertebrate forebrain and brain stem, it is likely that a hierarchy of molecular specification is established early, which controls patterns of gene expression within regional structures. Diffusible signals are likely to establish early patterns of expression of transcription factors (see above), which act further to promote patterns of inductive signals that control cellular diversity. Prochiantz and colleagues (Volovitch et al., 1993) suggested such a hierarchy in which the generation of diversity is tantamount to the formation of specific connections.

Genes involved in regulating dorsoventral and anteroposterior patterning in the forebrain have been

discovered (see above and Bulfone et al., 1993; Rubenstein and Beachy, 1998). The development of transverse domains in the forebrain is much less clear, and is particularly relevant to regionalization of the cerebral cortex. Boncinelli and co-workers (Boncinelli, Gulisano, and Broccoli, 1993; Simeone et al., 1992) have suggested that *Otx* and *Emx* family members, whose patterns of expression are overlapping, may participate. There is little evidence, however, for transcription factors that are expressed discretely in functional domains of the cerebral cortex. In fact, the broad patterns of expression reflect the general disruption of forebrain development that occurs upon mutation of *Otx1* and 2, *Emx-2* and *Bf-1* in mice (Suda, Matsuo, and Aizawa, 1997; Xuan et al., 1995). Mutation of *Emx-1*, which is expressed in all neo-, meso-, allo-, and paleocortical regions (Fernandez et al., 1998; Simeone et al., 1992), results in a very mild phenotype (Qiu et al., 1996; Yoshida et al., 1997). One possible mechanism driving cortical specification would involve regulation of gene expression by transcription factors that are expressed in complex, overlapping anatomic patterns. Specification of motor neuron pools occurs in this fashion (Pfaff and Kintner, 1998; Tanabe and Jessell, 1996). Thus, no single gene expression pattern can account for the unique characteristics of a specific set of motor neurons.

Neighboring cell-cell and subcortical-cortical interactions may promote cortical specification. Each of these could control the recently discovered regionalized patterns of expression of axon guidance molecules, which may mediate the formation of cortical circuits. At least four different families of guidance molecules exhibit regionalized patterns in the cerebral cortex during development (figure 2.2):

1. LAMP in meso- and allocortex (Horton and Levitt, 1988; Pimenta et al., 1995; Pimenta, Reinoso, and Levitt, 1996; Reinoso, Pimenta, and Levitt, 1996; Zacco et al., 1990) and neurotrimin (*Ntm*), a related Ig superfamily molecule, in a pattern complementary to LAMP in primary sensory regions (Struyk et al., 1995; Gil et al., 1997);
2. Eph receptor A5 in limbic cortical regions (Zhang et al., 1997) and its ligand, EphrinA5, with the most dense expression complementary in primary somatosensory cortex (Gao et al., 1998);
3. Cadherin family members cad-6 and cad-8, which are expressed in restricted parts of parietal and limbic cortex, respectively (Redies and Takeichi, 1996);
4. Semaphorin family members, which exhibit complex patterns of expression in different regions of the cortex (Skaliorea et al., 1998).

FIGURE 2.2 Diagram illustrating the expression patterns of several different guidance molecules in the cerebral cortex during embryonic development. Note that LAMP is expressed both in lateral regions of the cortex along the rhinal sulcus and medially in the prefrontal and anterior cingulate regions. LAMP does not extend into posterior midline regions. EphrinA5 is expressed heavily in dorsolateral parietal areas, complementary to the mostly rostral frontal expression of EphA5. Cadherin 6 has overlapping expression domains with EphrinA5, and cadherin 8 medially in a region of the cerebral wall that overlaps with both LAMP and EphA5. Patterns are drawn on a figure of the rat brain at embryonic day 17. (Reprinted with permission from Altman and Bayer, 1995.)

LAMP, *Ntm* and EphrinA5 have been shown specifically to mediate the growth of different populations of cortical and subcortical neurons (Gao et al., 1998; Gil et al., 1997; Mann et al., 1998).

What regulates the expression patterns of axon guidance molecules? We have focused on the potential inductive cues that control LAMP expression because the transplant studies showed that changes in the environment of cortical progenitor cells can alter their limbic areal fate. Thus, under the appropriate conditions *in vivo*, progenitors that normally give rise to sensorimotor neurons can generate LAMP⁺ neurons with limbic connections. The transplant paradigm is not designed to identify the specific molecular components that mediate these changes in progenitor cell fate. We developed a cell culture system in which we harvested progenitors from the early cerebral wall (embryonic day 12), prior to neuron production in the rat cerebral cortex (Ferri and Levitt, 1993). The studies initially documented a rather remarkable interaction between a diffusible growth factor, transforming growth factor alpha (TGFα) and collagen type IV, which collaborate to induce LAMP expression by

neocortical progenitors when they differentiate into neurons (Ferri and Levitt, 1993). TGF α is the CNS ligand that activates the EGF (ErbB1) receptor. The growth factor–matrix interaction was not as surprising as the type of matrix that was required. This is because collagen type IV is usually associated with basement membranes, as in blood vessels. Laminin, fibronectin, and polylysine or polyornithine were unable to substitute for collagen type IV. A mapping study confirmed that collagen type IV is expressed heavily, but transiently, in the ventricular zone of the rat cerebral wall by E11 (Eagleson, Ferri, and Levitt, 1996). The inductive nature of EGFr activation is exhibited only on progenitor cells; neurons fail to respond. The induction of LAMP by EGFr activation is cell cycle–dependent; this is because progenitors must be exposed for a complete cell cycle in order to respond to the inductive signal (Eagleson et al., 1997; Ferri and Levitt, 1995). In fact, cells undergoing their final cycle failed to express LAMP, even though they had been exposed to the inductive signal (Eagleson, Ferri, and Levitt, 1997). Furthermore, we found that induction resulted in LAMP expression in all daughter cells. Clonal analysis using retroviruses that express a reporter gene allows sibling cells to be followed over time through subsequent generations in vitro. The studies showed that of all the progenitor cells that responded to TGF α , more than 90% of the clones generated by these cells were homogeneous in reference to LAMP expression. The data suggest that the inductive response is represented by faithful inheritance of the LAMP phenotype. This feature is even exhibited in the absence of inductive signals in vitro by limbic progenitors. Those progenitors isolated from presumptive limbic regions of the cerebral wall produced LAMP⁺ neurons. Moreover, all the cells comprising multicell neuronal clones, arising from limbic progenitors, were LAMP⁺. Multicell clones are formed by progenitors that divide more than once in vitro, demonstrating that even through several cell divisions, all limbic progeny upon differentiation expressed LAMP. These results suggested that limbic progenitor cells received an inductive signal in vivo, prior to harvesting, and were able to remember this signal through several cell divisions (Eagleson et al., 1997).

LAMP is clearly a phenotypic marker that is expressed early. But are all features that are unique to areas of cortex specified? This has not been examined in detail for Ntn or the cadherins; however, recent studies in our laboratory indicate that EphrinA5 expression, which begins at about embryonic day 16 in the rat dorsal parietal region, is regulated differently than LAMP. Progenitor cells isolated from the presumptive sensorimotor domain of the cerebral wall at embryonic day 12 do not express EphrinA5 when neuronal differentiation occurs

(K. Eagleson, R. Zhou, and P. Levitt, unpublished observations). Harvesting of the same region of the cerebral wall 4–5 days later results in robust EphrinA5 expression. It is possible that the inductive signals that regulate EphrinA5 expression were not active at the time of progenitor cell harvesting. Clearly, however, each axon guidance cue may be under different regulation.

Consequences of anomalies in cortical development

Defects in development of the CNS are now believed to underlie, in part, the etiology of neuropsychiatric disorders, such as schizophrenia (Bloom, 1993; Kotrla, Sater, and Weinberger, 1997; Raedler, Knable, and Weinberger, 1998; Weinberger, 1995). The cerebral cortex is an obvious candidate site of developmental alterations because the establishment of lamination and functional areas is required for normal circuit formation. In particular, it has been suggested that regions of the cerebral cortex that mediate cognition, emotional state, and learning and memory (so-called limbic system structures) may be involved in developmental defects leading to pronounced psychopathology. In particular, the absence of pronounced cortical neuropathology in neuropsychiatric disorders suggests that there probably are not major defects in the milestone events of cell proliferation, migration, and cellular differentiation. We are only beginning to learn the consequences of how modest changes in cell cycle regulation or early inductive events in the forebrain might affect pattern formation. For example, gene knockout studies of individual transcription factors may result in little or no altered phenotype (Rubenstein and Beachy, 1998). There are examples of a range of defects, from the mild to the profound. Mutations in Emx-2 or Bf-1 result in severe forebrain malformations. Double knockout of Dlx1 and Dlx2 is required in order to see changes in forebrain organization (Anderson et al., 1998); single mutations of either gene result in minimal changes in brain organization. In the double knockout, Anderson et al. (1998) found that interneuron populations that arise from the ganglion eminence fail to form, and thus the cerebral cortex in the double mutant have reduced numbers of interneurons. Such alterations in early events of neurogenesis could generate functional defects. There are only a few examples of gene mutations that may be involved in the formation of specific cortical circuits, and they have yet to yield identifiable phenotypes (for example, Semaphorin III; see Catalano et al., 1998). As with the Dlx genes, abnormal phenotypes may arise through the mutation of several genes that encode different guidance cues, which normally work in concert to mediate circuit

formation in the cerebral cortex. The discovery of transcription factors that are expressed in discrete, but overlapping patterns may be an important element in future investigations. It is possible that mutations in any one or combination of these factors may result in altered cortical phenotypes, which, when examined at the cellular level, may yield clues that link psychopathology with developmental alterations during formation of the cerebral cortex.

3 A Comparative Perspective on the Formation of Retinal Connections in the Mammalian Brain

LEO M. CHALUPA AND CARA J. WEFERS

ABSTRACT Recent studies dealing with the formation of retinal projections reveal that mammalian species employ diverse ontogenetic strategies to attain the connectional specificity evident at maturity. Here we review work from our lab on the topographic organization of the retinocollicular pathway in carnivores showing a remarkable degree of precision throughout development, and contrast this with the diffuse mistargeting found in this pathway in the developing rat. We also consider the formation of retinogeniculate projections in the embryonic monkey. In this species, the early divergence of magnocellular and parvocellular pathways reflects the expression of cell-specific markers. The segregation of initially intermingled binocular projections occurs at a later stage, and during this period retinogeniculate fibers are in a state of continuous growth and elaboration. Unlike in the fetal cat, axonal side-branches are few and relatively constant in number throughout prenatal development. Thus, the formation of eye-specific inputs in the primate can best be accounted for by the loss of retinal ganglion cells whose fibers have innervated inappropriate territories rather than resorption of axonal processes. These phylogenetic differences may provide new insights into the multiple factors underlying the formation of connections in the mammalian visual system.

The quest to further our understanding of how the brain gets wired has involved the study of many different systems. In this daunting endeavor the connections of the eyes to retinorecipient structures in the midbrain and thalamus have long been considered favorite models. Consequently, we know a great deal about what occurs from the time that ganglion cells first innervate their target structures until the highly precise projection patterns found at maturity are established. A tacit assumption in this field has been the notion that the developmental events responsible for the formation of retinal connections are basically the same in different mammalian species. What occurs during the formation of the visual system in the rat is thought to apply, albeit at a different time scale, to the cat, monkey, and by extension to the

human. At the same time, no one doubts that at maturity the salient features of the visual system are strikingly different among species. This is certainly manifest when one compares the organization of retinal projections in the animals most commonly studied by developmental neurobiologists—the rat, cat, ferret, and monkey.

Here, we consider the results of recent experiments dealing with the development of the retinocollicular pathway in carnivores and retinogeniculate projections in the monkey. The results of these studies, when considered with respect to related work on these pathways in other species, suggest that different developmental strategies have evolved in animals occupying diverse phylogenetic and ecological niches for establishing their unique patterns of connections.

Topographic organization of developing retinocollicular pathways

Shortly after the introduction of axoplasmic-based tracing techniques, it was established that retinal projections initially innervate widespread regions of their target structures before becoming gradually restricted to eye-specific territories (reviewed in Chalupa and Dreher, 1991). For instance, in the retinocollicular pathway it was shown that, in the developing rat (Land and Lund, 1979) and cat (Williams and Chalupa, 1982), the projections of the left and right eyes initially innervate virtually the entire rostrocaudal extent of the superior colliculus. Particularly pronounced is the restructuring exhibited during ontogeny by the ipsilateral pathway which, at maturity, is limited to a patchy distribution within the rostral portion of the colliculus. The overall sequence of events depicted in these studies gave the impression that the early retinocollicular projection pattern was quite diffuse.

This impression was subsequently confirmed by retrograde and anterograde tracing studies of the rat's retinocollicular projection. After making a focal

LEO M. CHALUPA and CARA J. WEFERS Section of Neurobiology, Physiology and Behavior, University of California, Davis, Calif.

deposit of a fluorescent dye into the caudal pole of the superior colliculus of the newborn rat, O'Leary and colleagues (1986) found a large number of labeled ganglion cells scattered throughout the contralateral retina. Some degree of order was evident, however, since the topographically appropriate peripheral nasal retina contained the highest density of labeled cells. On the basis of such results, it was estimated that for every 100 retinal ganglion cells projecting to the topographically appropriate portion of the superior colliculus, about 14 neurons make gross topographic errors. Consistent with such a high error rate, the initial ingrowth pattern of retinocollicular fibers in the developing rat was also found to be diffuse in anterograde tracing experiments. After crystals of DiI were placed into a region of the temporal retina, crossed retinocollicular fibers were found to initially mistarget widely across both the rostrocaudal and the mediolateral axes of the colliculus (Simon and O'Leary, 1990, 1992).

When identical techniques were employed to study the developing retinocollicular pathway of carnivores (Chalupa, Snider, and Kirby, 1996; Chalupa and Snider, 1998), a very different impression of developmental specificity was obtained. Focal deposits of retrograde tracers into the superficial layers of the superior colliculus of fetal cats revealed that at all stages of development labeled cells were confined, with few exceptions, to a delimited region of the contralateral and ipsilateral retinas. Moreover, the location of retinal regions with a high density of labeled ganglion cells varied with the locus of the tracer deposit in the colliculus in a manner consistent with the topographic organization of the mature cat's retinocollicular pathway. Although some labeled ganglion cells were found to be scattered throughout the contralateral and ipsilateral retinas, such ectopic cells were very sparse in the fetal cat. Throughout development for every 100 cells projecting to the appropriate region of the colliculus, less than one ganglion cell was estimated to make a projection error. Surprisingly, the incidence of ectopic cells did not differ between the contralateral and ipsilateral retina, even though the overall density of crossed labeled cells was consistently greater than that of uncrossed cells.

A high degree of topographic specificity was also found when retinocollicular projections of developing ferrets were visualized by means of anterograde tracings following focal tracer deposits into the developing retina (Chalupa and Snider, 1998). Beginning with the period when the first axons enter the midbrain at embryonic day (E) 30, there is remarkable degree of order, both in the pattern of innervation and in the formation of terminal arbors within topographically appropriate regions

(figures 3.1 and 3.2). Although some misprojecting fibers were evident at all stages of development, these were relatively few and remained fairly constant throughout development.

Taken together, the results of the studies summarized above reveal striking differences in the degree of precision exhibited by the developing retinocollicular pathway of the rat as compared to that of the cat and ferret. There is evidence of massive gross mistargeting in the rat, while in carnivores such projection errors are the exception rather than the rule. These observations have clear implications for the factors that may be responsible for establishing orderly retinal projection patterns. Because the initial ingrowth pattern of retinal axons in the rat is very diffuse, topographic specificity must be instilled by some factor(s) other than directed axonal ingrowth. More specifically, the establishment of topographic specificity in the rat undoubtedly involves "pruning" of extensive collateral branches and axonal arborizations. By contrast, the precise projection pattern seen during development in carnivores would seem to suggest that axon ingrowth plays a major role in establishing retinotopic maps, although some refinement is required to establish the high degree of order found at maturity.

What accounts for the initially widespread ipsilateral retinocollicular projection revealed by intraocular tracing studies? Our investigations of the topographic organization of this pathway in developing cats and ferrets point to multiple factors. First, early in ontogeny uncrossed retinocollicular axons are characterized by widespread terminal arbors which gradually become restricted to attain their mature size. Second, some ganglion cells in the nasal retina project to the caudal portion of the ipsilateral colliculus. Such ganglion cells, which are normally lost during the course of development, appear to innervate the appropriate topographic location of the superior colliculus, but on the wrong side of the brain. Other factors, such as the elimination of axonal side-branches and the loss of ectopic ganglion cells, also contribute to this process; however, such refinements appear to be much less prominent in the carnivore retinocollicular pathway than has been shown to be the case in the developing rat (Simon and O'Leary, 1990, 1992).

Development of retinogeniculate projections in the fetal monkey

Retinogeniculate projections in the mature primate are characterized by several distinguishing features. In the primate, ganglion cells are separated into nasal and temporal hemi-retinas on the basis of their decussation patterns, so that all cells in the temporal retina project

FIGURE 3.1 Confocal montages of wholemounted superior colliculi at three developmental ages. In all panels the collicular border is outlined by a dashed line with the rostral edges denoted by arrows. The left side of each montage is contralateral to the implanted eye. The upper right corner of each panel shows flatmount of retina with black area denoting the DiI implant site. Filled circle represents the optic disk. T, temporal; S, superior. At E34, a contingent of retinal fibers has grown into ipsilateral colliculus, while only a few crossed fibers have reached the colliculus. Note the parallel trajectory of the fibers within the superficial layers. By E38, fibers have begun to ter-

minate in the topographically appropriate loci within the contralateral and ipsilateral superior colliculus. Although smaller in area, the contralateral terminal zone is much denser than the ipsilateral terminal zone. At the latest age, P0, a well-defined terminal zone is evident in both the contralateral and ipsilateral superior colliculus in topographically appropriate regions. Compared to E38 the ipsilateral terminal zone has restricted while the contralateral terminal zone has expanded. A few mistargeting fibers can be seen traveling past their respective terminal zones at each age. Scale bars: 1 mm for retina; 500 μ m for wholemount.

ipsilaterally while those in the nasal retina project to the contralateral side of the brain. In all other species some ganglion cells, distributed across the entire retina, project to the contralateral hemisphere, so that cells with crossed and uncrossed projections are intermingled within the temporal retina. Upon reaching the thalamus, primate ganglion cells project to the dorsal lateral genic-

ulate nucleus in an eye-specific manner, so that the contralateral eye innervates layers 1, 4, and 6 while the ipsilateral eye projects to layers 2, 3, and 5. Eye-specific projection patterns are found in other species with highly developed binocular vision, such as the cat and ferret. What distinguishes the primate from other species is that the major classes of ganglion cells also project in a

FIGURE 3.2 Sagittal section through the densest region of the ipsilateral terminal zone of the E38 animal shown in figure 11.1. The collicular border is outlined by a broken line, with the rostral (left) and the caudal (right) edges denoted by arrows. Note the perpendicular turn of the ipsilateral fibers toward the dorsal surface of the superior colliculus where they terminate in upper layers. Scale bar = 250 μ m.

laminar-specific pattern, with the large $P\alpha$ cells innervating magnocellular layers, 1 and 2, and the smaller $P\beta$ neurons projecting to parvocellular layers, 3 through 6. Thus, the primate retinogeniculate pathway is characterized by laminar specificity defined in terms of ocular domains as well as cell-specific patterns (figure 3.3). In

FIGURE 3.3 Schematic illustration of neuronal connections between the eyes and the LGN in the macaque monkey. The connections serving the left and right eyes might be parvocellular (P, about 80%), magnocellular (M, about 10%), or others (K, I, or S, about 10%; not shown). The different types of ganglion cells in the retina are intermixed although the percentage of P cells is higher in the central retina than at the periphery. In the LGN, layers 1 and 2 are magnocellular and layers 3 to 6 are parvocellular. In a given eye, the set of M ganglion cells that project to the contralateral LGN terminates in layer 1, whereas the cells that project ipsilaterally terminate in layer 2. The P ganglion cells project to layers 3 and 5 to the LGN on the same side, and 4 and 6 on the opposite side. For clarity, projections from just one eye are shown.

rows. Note the perpendicular turn of the ipsilateral fibers toward the dorsal surface of the superior colliculus where they terminate in upper layers. Scale bar = 250 μ m.

some species, the inputs of ON and OFF subclasses of ganglion cells are further segregated within sublaminae of the dorsal lateral geniculate nucleus (Stryker and Zahs, 1983), but this is not the case in the primate where the projections of both subclasses are intermingled within a single geniculate layer.

Studies on fetal monkeys have provided information about the formation of retinal decussation patterns, eye-specific laminar projections, as well as magno and parvo pathways. Below, we discuss the development of these fundamental features of the primate visual system and compare our findings to what has been learned from related studies on nonprimate species.

Retinal decussation

The organization of the fetal monkey's retinal decussation pattern was examined by plotting the distributions of labeled cells in both retinas in animals of known gestational ages that received large injections of HRP into the retinorecipient structures of one hemisphere (Chalupa and Lia, 1991). This revealed that throughout development virtually all retinal ganglion cells in the macaque monkey make a correct chiasmatic decision. Thus, even as early as E69, about 100 days before birth, less than 0.5% of all retinal ganglion cells innervate the inappropriate hemisphere. The fact that the nasotemporal decussation pattern of the fetal rhesus monkey is nearly identical to that observed at maturity indicates that retinal positional markers must play a key role in specifying the laterality of ganglion cell projections. Thus, it is likely that ganglion cells generated in the temporal retina are characterized by molecular markers different from those of cells in the nasal retina. Such position-derived cues could guide the distinct behaviors of ganglion cell axons when they arrive at the optic chiasm.

To gain further insight into this problem, we examined the organization of pioneer retinal axons in the embryonic rhesus monkey (Meissirel and Chalupa, 1994). The initial contingents of crossed and uncrossed optic axons were labeled by two different carbocyanine dyes which permitted their differentiation with confocal microscopy. This revealed that in the embryonic monkey, the uncrossed retinal fibers enter the optic tract well in advance of the crossed fibers, an observation noted previously in the embryonic mouse (Godement, Salaün, and Métin, 1987). When the crossed axons begin to enter the tract, they remain largely segregated from the uncrossed contingent of fibers. This shows that crossed and uncrossed retinal projections, which initially form the primate optic tract, follow distinct temporal and spatial ingrowth patterns. Such an orderly sequential ingrowth of pioneer retinal axons would be expected if chiasmatic cues were expressed very early in development. In the embryonic mouse it has been suggested that a combination of outgrowth promoting and inhibiting molecules (termed L1/CD44 array) is expressed by neurons in the developing optic chiasm and that this acts as a template for guiding the initial decussation pattern (Sretavan et al., 1994). It would seem reasonable to think that similar molecular cues are expressed by chiasmatic neurons in primate embryos, but this remains to be established. Moreover, the temporal and spatial segregation of crossed and uncrossed fibers indicates that the ingrowth of axons into the optic tract is not dependent upon interactions between fibers from the ipsilateral and contralateral eyes. Such an interaction has been inferred from studies on the developing mouse in which one eye was removed before the optic axons arrived at the chiasm (Godement, Salaün, and Métin, 1987), but this idea has not been supported by time-lapse video analysis of navigational patterns of crossed and uncrossed optic fibers (Sretavan and Reichardt, 1993).

Formation of retinogeniculate M and P pathways

The results summarized in this section have been described in greater detail by Meissirel (Meissirel et al., 1997), from which this account is derived.

Tritiated thymidine studies have revealed a curious mismatch between the birth order of P α and P β retinal ganglion cells and that of their target neurons in the M and P layers of the dorsal lateral geniculate nucleus. Within a given region of the retina, P β cells are born earlier than P α cells (Rapaport et al., 1992), but in the geniculate anlage neurons destined for the M layers are generated prior to those that will form the P laminae (Rakic, 1977). In the macaque embryo, the first retinal fibers (stemming from the contralateral eye) reach the

geniculate anlage by E48. By this age all geniculate neurons have been generated and have completed their migration, but despite this availability of target cells, the initial contingent of axons bypasses the dorsal thalamus to innervate the midbrain (figure 3.4A). The innervation of the geniculate begins several days later, when retinal fibers sprout short branches which terminate selectively within the medial segment of the nucleus (figure 3.4B). Crossed fibers innervate the medial segment first, and the uncrossed fibers follow this specific ingrowth pattern several days later (figure 3.4C). During this time period the geniculate undergoes a progressive rotation (figure 3.4E), and it is only when this process is largely completed (at E74) that the ventral region of the nucleus (formerly the lateral segment) begins to receive retinal inputs. At this stage, lamination of the geniculate has not occurred, so it is not possible to differentiate between parvo and magno layers. However, based on the outside-to-inside pattern of geniculate cell generation (Rakic, 1977), it can be inferred that the early innervated segment corresponds to what will become the parvo layers, while the later innervated lateral portion of the nucleus will differentiate into the magno laminae (figure 3.4E). Thus, the temporal sequence for “hooking-up” the retinogeniculate pathway in the primate embryo follows the order of ganglion cell generation (i.e., P β before P α) rather than the temporal sequence of target cell generation, in which magno cells are generated before parvo neurons.

At maturity, retinogeniculate arbors stemming from the P α and P β ganglion cells can be differentiated on the basis of their distinctive morphologic features (Conley and Fitzpatrick, 1989). Remarkably, such morphologic differences become evident in the primate embryo as soon as terminal arbors become elaborated (by E95).

The highly specific ingrowth pattern characterizing the formation of parvocellular and magnocellular retinogeniculate pathways was unexpected because left and right eye inputs to the different laminae of this structure were shown to be initially completely intermingled (Rakic, 1976). Indeed, the retinogeniculate pathway of the fetal primate has long been considered the classic example of exuberant projections and subsequent refinement in the developing brain. Our findings reveal, however, that when functional components of this pathway are considered, namely parvocellular and magnocellular inputs, a different picture emerges. Refinements of early projections may not be required in this case because the parvo and magno subsystems seem to follow laminar-specific cues which appear to guide the axons of P α and P β cells to the appropriate segments of the primate geniculate.

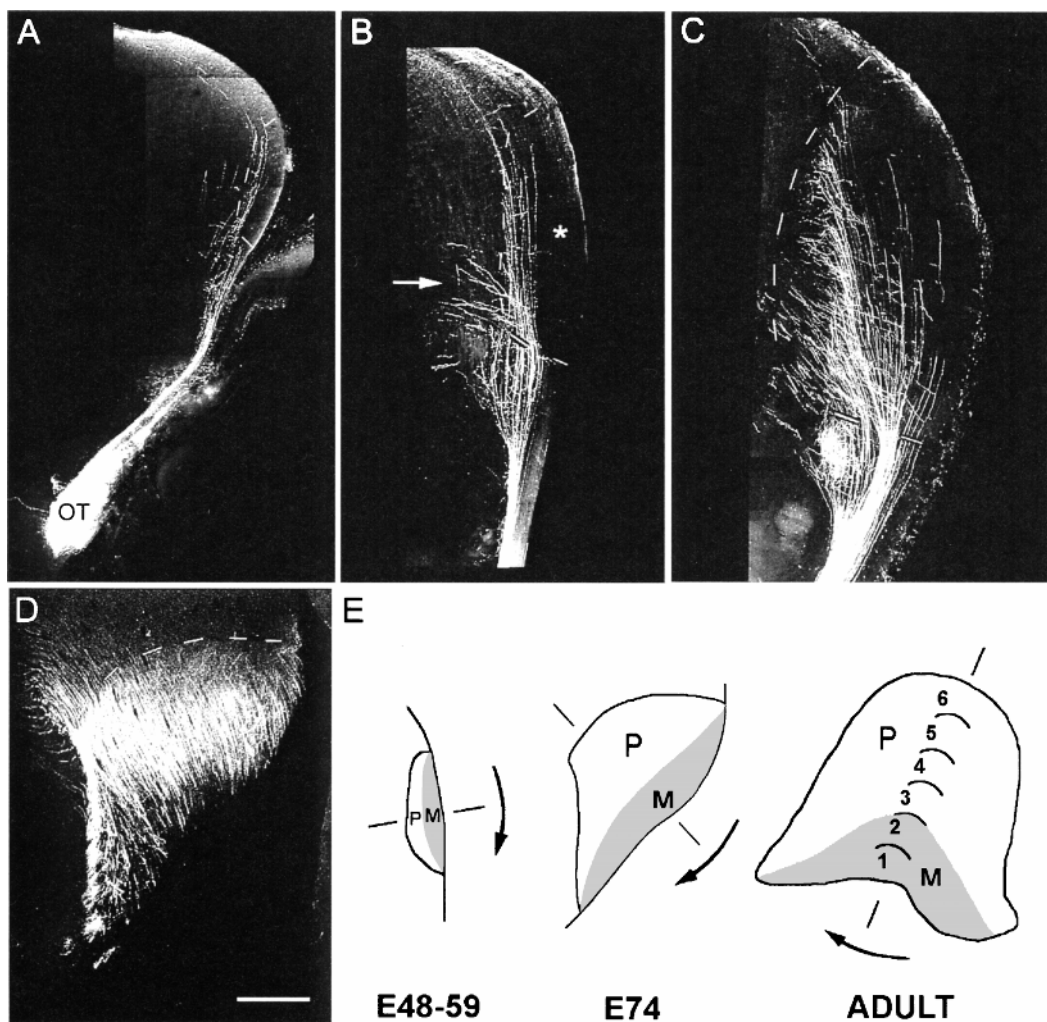

FIGURE 3.4 Photomontages of confocal images through representative coronal sections of the diencephalon showing the distribution of DiI-labeled retinal axons in the embryonic thalamus. (A–D) Dashed lines indicate the border of the dorsal lateral geniculate (dLGN) with a dorsal orientation to the top and a lateral orientation to the right. (A–C) The contralateral side to the DiI optic nerve implants. (A) At E48, retinal axons navigate the contralateral optic tract before being deflected away from the pial surface as they approach the geniculate. A few axons course dorsally past the dLGN toward the midbrain. (B) At E53, there is greater ingrowth of retinal fibers, some of them elaborating medially directed branches. Note that the lateral aspect of the dLGN remains totally devoid of retinal axons (*). Branches derived from the axon trunks are concentrated at the bottom third of the dLGN, and in some cases these extend past

its medial border in the external medullary lamina (arrow). (C) At E64, an increasing number of axonal branches invade the medial region of the nucleus. Note that, at this age, the lateral segment of the dLGN is still virtually free of retinal afferents. The section shown is from the rostral part of the dLGN, but essentially the same pattern is observed throughout the rostro-caudal extent of the nucleus. (D) At E74, DiI crystals were implanted into the optic tract to reduce the distance of diffusion. Virtually the entire extent of the nucleus now receives a retinal innervation. The coronal section is from the caudal aspect of the dLGN. (E) Schematic representation of the dLGN rotation (arrows) from E48 to adulthood. The presumptive M layers (shaded area) rotate from a lateral to a ventral position whereas the presumptive P layers rotate from a medial to a dorsal position. Scale bar: A–C, and E, 500 μm ; D, 400 μm .

Such observations imply that these two main classes of primate retinal ganglion cells must express different molecular markers that permit their axons to react differentially to putative laminar-specific cues. In the adult macaque retina, antibodies generated against two different gene products (termed Brn-3a and Brn-3b) have

been shown to differentially label $P\alpha$ and $P\beta$ ganglion cell populations (Xiang et al., 1995). Application of these antibodies to the embryonic retina revealed that Brn-3a and Brn-3b positive cells could be visualized at very early stages of development. This was observed shortly after ganglion cells had undergone their final division,

and even before they had migrated from the ventricular layer to the ganglion cell layer. These findings provide evidence for the early divergence of P α and P β ganglion cells. Furthermore, they reveal an essential link between distinct cell classes and the high specificity exhibited by these neurons when their fibers innervate the parvo and magno segments of the geniculate.

This suggests that M and P streams in the primate retinogeniculate pathway could be established on the basis of the expression of molecular cues, without the involvement of activity-mediated refinements. This inference is certainly consistent with the evidence summarized above. This interpretation is also in line with what is known about the functional development of mammalian retinal ganglion cells. Patch-clamp recordings from ganglion cells isolated from the fetal cat retina indicate that very early in development these neurons are incapable of generating action potentials (Skaliora, Scobey, and Chalupa, 1993). To a large degree this reflects the low density of sodium channels at early stages of development (Skaliora, Scobey, and Chalupa, 1993), but ontogenetic fluctuations in other conductances and channel properties associated with spike generation have also been documented by means of voltage-clamp recordings (Skaliora et al., 1995; Wang et al., 1997; Robinson and Wang, in press). By extrapolation from these studies on the fetal cat, it seems unlikely that ganglion cells in the embryonic primate are capable of firing action potentials at the time that the parvo and magno pathways are being established. By contrast, several weeks before the segregation of overlapping binocular projections has begun all retinal ganglion cells can discharge action potentials to depolarizing current injections (Skaliora, Scobey, and Chalupa, 1993).

Formation of eye-specific projections

More than twenty years ago, Rakic (1976) discovered, by means of intraocular injections of tritiated amino acids, that the projections of the two eyes innervate the entire dorsal lateral geniculate before segregating into eye-specific laminae. The separation of initially intermingled binocular projections occurs later in development (from about E85 until E120) than the formation of parvo and magno pathways, as discussed above. Analogous experiments on numerous species have shown that such binocular overlap of retinal projections is a common feature of mammalian development, although the degree of binocular overlap exhibited by different species can vary substantially (cf. Chalupa and Dreher, 1991). There is also evidence that the segregation process reflects binocular interactions. Removal of one eye at the time that projections overlap results in the maintenance of the

widespread pattern from the remaining eye (Rakic, 1976; Chalupa and Williams, 1984). Such binocular interactions are thought to reflect activity-mediated events since blockade of spontaneously generated retinal activity induces marked changes in the geniculate territory innervated by the two eyes (Penn et al., 1998).

At a cellular level the early intermingling of left and right eye inputs could be accounted for by two non-mutually exclusive mechanisms. As shown diagrammatically in figure 3.5, one possibility is that individual retinal fibers could be more extensive during development than at maturity, with axons from the two eyes innervating overlapping territories. Such exuberance at the single fiber level could reflect larger terminal arbors as well as the presence of transient axonal side-branches. An alternative hypothesis is that terminal arbors of individual fibers are not exuberant, but some innervate inappropriate territories destined to be the exclusive domain of the other eye. Thus, fibers from the ipsilateral eye might innervate layer 1, and subsequently such inappropriate projections would be eliminated during the period of developmental cell death.

A morphologic analysis of single retinal fibers in the fetal cat revealed that during the prenatal binocular

FIGURE 3.5 Schematic of two possible scenarios for the formation of retinogeniculate axons into eye-specific layers in the dLGN. The black outline represents a coronal section of the LGN. The black lines represent contralateral projections; ipsilateral projections are shown in gray. In the adult, the layers of the LGN (numbered) are denoted by stippled lines. In the prenatal sections, a layer is represented for clarity. One possibility is a loss of side branches, and a restructuring of the terminal arborizations (A). The alternative is that optic fiber loss underlies the formation of mature projection patterns (B). Our data suggest the latter alternative.

FIGURE 3.6 Confocal photomontages of retinogeniculate axons at different embryonic days (E): E77 (A), E95 (B), and E112 (C). Note that throughout prenatal development these axons

are nearly devoid of side branches and show continuous growth and elaboration of the terminal arborization. Cal bars = 50 μ m. White arrowheads point to side branches in A.

overlap period there are numerous axonal side-branches (Sretavan and Shatz, 1984). These often span across territories destined to become eye-specific during the course of normal development. Furthermore, the loss of

such axonal processes corresponds to the time when binocular segregation occurs. Interestingly, the terminal arbors did not show any transient increase in size during the binocular overlap period. These findings provide a

clear-cut account of the cellular basis of binocular overlap and segregation: The overlap reflects the presence of axonal side-branches, while the segregation is due to the loss of such processes.

In the more than two decades since Pasko Rakic showed binocular overlap of retinogeniculate projections in the fetal monkey, it seems remarkable that no one has studied retinogeniculate fibers in the prenatal primate. To some degree, this lacuna reflects the common assumption that what was found in the cat also applies to the monkey.

Recently, we undertook a study of the morphologic characteristics of single retinogeniculate axons in fetal monkeys (Snider et al., 1999). Such an investigation seemed a logical extension of the work described above. We were also motivated by increasing evidence of species differences in the developmental specificity exhibited by other components of the mammalian visual systems (Chalupa and Dreher, 1991). In particular, we were interested in determining whether the axonal side-branches, found to be prevalent in the cat during the binocular overlap period, would also be present in the fetal monkey. Retinal fibers were labeled by implanting single crystals of the fluorescent tracer DiI into the fixed optic tract, yielding complete labeling of single axons as visualized by confocal microscopy.

To date, we have analyzed more than 90 retinogeniculate fibers obtained from fetal animals spanning in age from E78 through E120. The youngest age is near the peak of the binocular overlap period and the oldest is when segregation is already well underway (Rakic, 1976). Examples of retinogeniculate fibers at E77, E95, and E112 are shown in the photomontages in figure 3.6. Several key features are clearly evident. First, axon terminals are yet to form in the youngest animal, while at older ages they become increasingly more complex and elaborate. Importantly, there is no indication that terminal arbors are greater in size at the time when binocular overlap is near its peak. Detailed measurements of a number of salient parameters, including the size and complexity of terminal arbors at four different ages, provided quantitative support for the impression obtained from the raw data (not shown). This was not unexpected since, as indicated above, retinogeniculate fibers of the fetal cat also showed no sign of retrenchment during the course of development. What was distinctive in the monkey embryos was the paucity of axonal side-branches. Throughout the binocular overlap period, retinal fibers in the magno and parvo segments of the geniculate were characterized by very few such processes. Moreover, the low incidence of axonal side-branches remained relatively

constant throughout the development period of binocular segregation.

To convince ourselves that this lack of transient axonal branches reflected a genuine species difference rather than some spurious methodological factor, we made similar deposits of DiI into the fixed optic tract of the fetal cat at E50, near the peak of the binocular overlap period. This revealed numerous axonal side-branches, in agreement with the report of Sretavan and Shatz who used HRP deposits in an *in vitro* preparation to label fetal cat optic fibers. This indicates that there are genuine differences between the cat and monkey in the cellular factors responsible for the binocular overlap and subsequent segregation of retinogeniculate projections: Resorption of axonal side-branches plays a role in this process in the fetal cat, but not in the monkey embryo.

During the segregation of binocular projections, there is a massive loss of optic axons in both the fetal monkey (Rakic and Riley, 1983a) and the fetal cat (Williams et al., 1986). Such loss of axons, which reflects the normal death of ganglion cells, could account entirely for the formation of eye-specific projection patterns. This idea was originally put forth by Rakic (1986), and our findings are entirely in accord with his suggestion. Moreover, this would also explain the observation that prenatal removal of one eye results in an increase of optic fibers in the remaining eye (Rakic and Riley, 1983b), which is concomitant with an expansion of the retinogeniculate projections stemming from the remaining eye. Monocular enucleation in the fetal cat during the binocular overlap period also results in an increase in the ganglion cell population (Chalupa, Williams, and Henderson, 1984) and a corresponding increase in the number of fibers (Williams, Bastiani, and Chalupa, 1983) in the remaining eye and optic nerve as well as an expanded retinogeniculate projection (Chalupa and Williams, 1984). Thus, it seems reasonable to think that loss of retinogeniculate axons is involved in forming eye-specific projection patterns in both the monkey and cat. The key feature distinguishing the monkey from the cat is the presence of transient axonal side-branches in carnivores.

Concluding remarks

The available evidence clearly indicates that there are marked species differences in the developmental events leading to the formation of certain key attributes of retinal projection patterns. In one respect, this complicates our efforts to understand how neuronal connections are formed in the developing brain. On the other hand, the ontogenetic variations exhibited by different species provide an opportunity for developmental neurobiologists

to assess the problem from a fresh perspective. By considering why one class of cells (for instance, the retinocollicular projection of the rat as compared to that of the cat) behaves differently from another could expand the scope of the enquiry to a new level of analysis. To understand how retinal ganglion cells make their precise patterns of connections, it could prove illuminating to consider why ganglion cells in different animals (and even different classes of cells in the same animal) hook up with their target neurons by means of different strategies. What's different and what's common during the development of mammalian retinofugal pathways? Until this issue is resolved, the task of developmental neurobiologists will not be completed.

4 Formation, Elimination, and Stabilization of Synapses in the Primate Cerebral Cortex

JEAN-PIERRE BOURGEOIS, PATRICIA S. GOLDMAN-RAKIC, AND PASKO RAKIC

ABSTRACT The formation of synaptic connections in the primate brain is a protracted and complex process that lasts for decades. We have performed a systematic examination of synaptogenesis in the cerebral cortex of the macaque monkey from the fortieth day of the six-month embryonic period through 30 years of age, identifying five distinct phases of synaptogenesis. In the five major cytoarchitectonic areas so far examined (visual, somatosensory, motor, limbic, and prefrontal), the first three phases of synaptogenesis proceed concurrently in different areas at a rate resistant to experimental manipulation. In contrast, the fourth phase, in which there is high synaptic density, is more malleable, i.e., subject to activity-dependent stabilization and presumed molecular changes in synaptic strength. This phase begins shortly after birth and continues until puberty. The fifth phase, which begins after sexual maturity and extends into old age, is characterized by a very slow decline in synaptic density. The absence of ultrastructural signs of synaptogenesis in the fifth phase indicates either a lack of new synapse formation or an extremely low turnover of synapses in the normal adult primate neocortex. The stability of synaptic contacts throughout adult life would be a biological advantage for the storage and preservation of acquired knowledge.

The cerebral cortex contains by far the largest proportion of synapses in the human brain (Szentagothai, 1978). Although the timing and status of synaptic connections form the basis of all theories of human psychological development, quantitative information on synaptogenesis has been lacking. To provide insight into mechanisms of development and maintenance of cortical synapses in primates, we have examined the course of synaptogenesis in the macaque monkey under normal and experimental conditions. The cellular organization and functional parcellation of cerebral cortex in this Old World monkey is remarkably similar to that of the hu-

man neocortex (e.g., Polyak, 1957; Shkol'nik-Yarros, 1971; Mountcastle, 1997). The primary visual cortex of the macaque monkey has proved an extremely useful model for analyzing developing connections, synaptoarchitectonics, chemoarchitectonics, plasticity, and the physiology of the primate neocortex (e.g., Hubel, Wiesel, and LeVay, 1977; Zielinski and Hendrickson, 1992; Rakic, Gallager, and Goldman-Rakic, 1988; Meissirel et al., 1997). It is also considered an unexcelled model for understanding human perceptual development (e.g., Teller, 1997, and chapter 6 of this volume).

The biological development of the primate neocortex entails a prolonged and highly orchestrated cascade of cellular events including, successively, the production, migration, and differentiation of neurons (for review, see Rakic, 1988, and chapter 1 of this volume). These early developmental events are followed by a more region-specific elaboration of dendritic and axonal processes (Rakic, 1976; Goldman-Rakic, 1987; Schwartz and Goldman-Rakic, 1991; Barone et al., 1995), culminating in an intricate pattern of synaptic contacts formed between ensembles of local and distant neurons. Using quantitative electron microscopy, we have delineated the kinetics of synaptogenesis in five major functionally distinct cortical areas of the macaque monkeys from conception to old age (Rakic et al., 1986; Bourgeois and Rakic, 1993; Bourgeois, Goldman-Rakic, and Rakic, 1994; Zecevic and Rakic, 1991; Zecevic, Bourgeois, and Rakic, 1989; Granger et al., 1995). The density of synapses per unit volume of neuropil has been estimated using stereological corrections for changes in synaptic size during development. This approach has also provided information on the overall density and number of synapses as well as synaptic localization (on dendritic spines or shafts, and cell somas) and nature (symmetric/asymmetric). These parameters pertain to the entire spectrum of synapses within the areas of interest—those arising locally as well as those from distant sources through long-tract afferents. Thus, our approach does not specify how individual pathways

or circuits contribute to the overall changes observed. However, quantification of the course of synaptogenesis across various functional domains sets the stage for more specific analyses and is essential for understanding the interactions between genetic and experiential influences on the scheduling, number, and pattern of synaptic connections. To that end, we have manipulated visual sensory input in two ways—advancing it through premature delivery on the one hand, and eliminating it by early enucleation in utero on the other—then examined the effect of these manipulations on the course of synaptogenesis in the cerebral cortex. We have also tracked synaptogenesis into old age—from puberty to 30-plus years. This chapter describes these various findings and discusses them in the context of human cognitive development.

Kinetics of synaptogenesis

Examination of the quantitative data obtained in a series of studies conducted in the past decade indicates that the course of synaptogenesis can be subdivided into several distinct phases, schematically illustrated in figure 4.1. The methodological details and data are available in the original publications (Bourgeois and Rakic, 1993; Bourgeois, Goldman-Rakic, and Rakic, 1994; Zecevic and Rakic, 1991; Zecevic, Bourgeois, and Rakic, 1989; Granger et al., 1995).

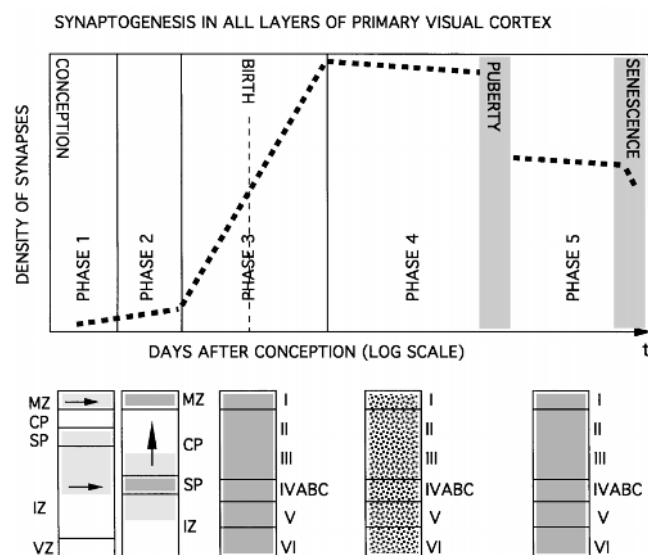

FIGURE 4.1 Changes in the relative density of synapses (dotted line in the upper frame) as a function of days after conception expressed on a log scale on the abscissa (t), in the primary visual cortex of the macaque monkey, during normal development. Five different phases of synaptogenesis are identified between conception and death. Each phase is superimposed above the density distribution of synapses in the cortical layers of the neocortex represented at the bottom of the figure. Abbreviations: CP, cortical plate; IZ, intermediate zone; MZ, marginal zone; SP, subplate.

Phase 1: The *precortical phase* of synaptogenesis in macaque embryos begins around embryonic (E) day 40 and lasts for two to three weeks, coinciding with the onset of neurogenesis and the formation of the cortical plate (Rakic, 1981, and chapter 1 of this volume). This phase is termed the precortical phase because synapses are first observed (in low density) in the marginal zone (prospective layer I) and in the subplate zone situated below cortical plate before emerging in the cortical plate itself. These early synapses are formed in part by axons originating from subcortical structures (horizontal arrows in figure 4.1). A similar distribution of early synapses has been observed in the initial phases of synaptogenesis in the human fetal cerebrum (Molliver, Kostovic, and Van der Loos, 1973; Zecevic, 1998).

Phase 2: The *early cortical phase* from E70 through E100 is characterized by the emergence of synapses in the cortical plate. These synapses are formed during the peak of neurogenesis and active migration of neuroblasts through the developing cortical plate (Rakic, 1972, 1988). An inside-out sequence of synaptic appearance appears to follow the radial penetration of axonal projections from the thalamus and from other cortical areas, either preceding (as in the primary visual cortex; cf. Bourgeois and Rakic, 1993), or following (as in the prefrontal cortex; cf. Bourgeois, Goldman-Rakic, and Rakic, 1994), their segregation into cortical columns (vertical arrow in figure 4.1; see also Rakic, 1981). Virtually all synapses during this phase are formed on the dendritic shafts of neurons.

Phase 3: This, the *rapid phase* of synaptogenesis, begins two months before birth (between E90 and E100) after most neurons have been generated; however, our data indicate that it is not directly linked to the end of neurogenesis (Granger et al., 1995). These new synaptic junctions are formed mainly on the dendritic spines coincident with the proliferative growth of dendritic and axonal arbors of intracortical and extracortical neurons (figures 4.2 and 4.3). Once initiated, this phase proceeds uninterruptedly until the maximal density of synapses per unit volume of neuropil is reached, during the second and third months of postnatal life.

Phase 4: This phase of *high synaptic density* in the macaque monkey lasts for about two years, from infancy to adolescence, and ends with a decline during puberty in the third year of life. We refer to it as the “plateau” phase because the mean density of synapses (about 600–900 million synapses per cubic millimeter of neuropil) is substantially above the adult level during most of this phase (Bourgeois and Rakic, 1993). The end of phase 4 is dominated by a significant decline in synaptic density, mainly due to the loss of asymmetric synapses located on dendritic spines (figures 4.2 and 4.3). Interestingly,

SYNAPTogenesis IN LAYER III OF PRIMARY VISUAL CORTEX

FIGURE 4.2 Changes in the relative densities of two different classes of synapses as a function of days after conception expressed on a log scale on the abscissa (t), in supra-granular layer III of the primary visual cortex of the macaque monkey, during normal development. During phase 2 a first wave of synaptogenesis occurs on dendritic shafts (black line), followed two weeks later by a second wave of synaptogenesis on the dendritic spines (dotted line) of the same neurons. During phase 3, before birth, the proportions of these classes of synapses are reversed. The same pattern of synaptogenesis is observed during the first three phases of synaptogenesis in all cortical layers, as well as in the cortices of all mammalian species, suggesting the existence of highly conserved mechanisms. In contrast, during phase 4, *en plateau*, the kinetics of these waves of synaptogenesis differ from that observed in granular layer IVC (cf. figure 4.3).

the number of symmetric synapses on shafts remains relatively steady throughout this period (Bourgeois, Goldman-Rakic, and Rakic, 1994; Bourgeois and Rakic, 1993; Zecevic, Bourgeois, and Rakic, 1989; Zecevic and Rakic, 1991).

It should be mentioned that the decline in synaptic density appears to begin earlier in the visual and somatosensory cortex than in the prefrontal association cortex. Nevertheless, at the time of sexual maturity synaptic density descends to adult levels in all areas of the macaque cortex examined to date, both in our laboratory (see above) and in other laboratories (e.g., see Zielinski and Hendrickson, 1992; Anderson et al., 1995). A similar magnitude of synapse loss during puberty has also been observed in electron microscopic studies in human (see figure 4.5 and Huttenlocher and Dabholkar, 1997) and mouse cortex (De Felipe et al., 1997)—a finding that has received indirect support from brain imaging studies in the macaque (Jacobs et al., 1995) and human cortices (Chugani, Phelps, and Mazziotta, 1987).

Although arbitrarily included in phase 4, we recognize that the period of rapid loss of synapses occurring during puberty could be considered a separate phase with its own cellular mechanisms. Our findings indicate that labile synapses that will not stabilize during

SYNAPTogenesis IN LAYER IVC OF PRIMARY VISUAL CORTEX

FIGURE 4.3 Changes in the relative densities of two different classes of synapses as a function of days after conception expressed on a log scale on the abscissa (t), in granular layer IVC of the primary visual cortex of the macaque monkey, during normal development. The same pattern of synaptogenesis is observed during the first three phases of synaptogenesis as in cortical layer III (see figure 4.2). However, during phase 4, *en plateau*, these two classes of synapses display distinct waves: a short wave of synapses on dendritic spines, and a protracted wave of synapses on dendritic shafts. This is different from the protracted plateau phase 4 of synaptogenesis on dendritic spines observed in supragranular layer III (see figure 4.2).

the long phase 4 are being eliminated during this phase. As frequently mentioned in textbooks, the period around puberty corresponds to a “freezing” of personality and a decline in neural plasticity for acquisition of certain capacities or skills. For example, 12 years of age in humans corresponds to the age at which second languages are no longer acquired with relative ease and without an accent (Johnson and Newport, 1989). Such observations may be explained by the stabilization of the final number of synapses at this period of life.

Phase 5: This last phase of *synaptic stability* begins in the third year of macaque life and lasts for the next three decades of adulthood until the density of synapses slowly but steadily declines with apparent acceleration during senescence (figure 4.1). The stages of synaptogenesis, as they have been discriminated in the studies of the human neocortex, are not entirely concordant with the five phases we have described in monkeys (Huttenlocher and Dabholkar, 1997). Although there is as yet no universal convention for comparative purposes, it is nevertheless clear that the phases of neocortical synaptogenesis in humans are analogous to those in monkeys and also significantly protracted in time as in the macaque (figure 4.5; see also Bourgeois, 1997). Importantly, major aspects of synaptoarchitecture in cortical networks during this period remain unchanged. As adulthood is the most prolonged period of primate life and adult synaptogenesis is of great interest, we have

SYNAPTogenesis IN LAYER IVC OF PRIMARY VISUAL CORTEX

FIGURE 4.4 Changes in the relative densities of two different classes of synapses as a function of days after conception expressed on a log scale on the abscissa (t), in granular layer IVC of the primary visual cortex of the macaque monkey after an early bilateral enucleation was performed during phase 1 of synaptogenesis (arrow). The same pattern of synaptogenesis unfolds normally during the first three phases (see figures 12.2 and 12.3). However, during phase 4, *en plateau*, the second reversal of densities of synapses on dendritic spines (dotted line) and shafts (black line) does not take place.

examined several thousand photomicrographs in search of ultrastructural evidence of new synaptic connections or their turnover during this period. While we observed growth cones and immature types of contacts or degenerating forms of connections during the formative stages (phases 1–4), we failed to observe any of these markers of new synaptic connections during this three-decade period of adult life. We cannot exclude the possibility that a small number of such events may escape detection. However, the addition of synapses is certainly not cumulative in the primate cerebral cortex since both the density of synapses and their numbers remain stationary during the long life span and, if anything, their numbers slowly decline. A similar lack of evidence for any increase in the density or absolute number of synapses has been observed in other primates (Zielinski and Hendrickson, 1992; Anderson et al., 1995), human (Huttenlocher and Dabholkar, 1997), and in mouse cerebral cortex (De Felipe et al., 1997).

NUMERICAL STABILITY OF SYNAPSES DURING ADULTHOOD The finding that the density and number of synapses becomes stabilized after puberty stands in contrast to earlier reports that learning induces the formation of additional synapses in vertebrate and invertebrates (e.g., Greenough and Bailey, 1988; Bailey and Kandel, 1993). More specifically, observations in rats suggest that experience, both in developing and adult rodents, can induce *de novo* formation of synapses, resulting in a net in-

SYNAPTogenesis IN HUMAN CEREBRAL CORTEX

FIGURE 4.5 Changes in the relative density of synapses in the human cerebral cortex as a function of days after conception expressed on a log scale on the abscissa (t). Data are from Huttenlocher and Dabholkar (1997). Only phases 3, 4, and 5 are represented here. The same phases of synaptogenesis are observed in both the primary visual cortex (black line) and prefrontal cortex (dashed line). Note that phase 4 is longer in the prefrontal cortex than in the striate cortex.

crease in their absolute number after each episode of associative learning (Greenough and Alcantara, 1993). These changes should be particularly evident in primates whose life span lasts for decades. However, this mechanism of experience-induced synaptogenesis is not supported by any study in primates including human, whose adult brain is characterized more by homeostasis or a slow but steady decrease of synapses in all layers and areas of the cerebral cortex during adult life (see phase 5 and figures 4.1 to 4.5; see also Bourgeois and Rakic, 1993; Bourgeois, Goldman-Rakic, and Rakic, 1994; Zecevic and Rakic, 1991; Zecevic, Bourgeois, and Rakic, 1989; Zielinski and Hendrickson, 1992; Anderson et al., 1995; Huttenlocher and Dabholkar, 1997). Significantly, a recent study in mice also failed to reveal evidence of an increase in density or absolute number of synapses in the rodent cerebral cortex after sexual maturity (De Felipe et al., 1997). Thus, when estimates of synaptic number or density are based on stereological methodology, the results fail to show net increases in cortical synapses after puberty in any of the species studied to date, despite the extensive opportunities, particularly in humans, for acquisition and accumulation of long-term memories.

This model of synaptic plasticity, without formation of additional synapses, is also supported by the recent ex-

perimental and ultrastructural analysis of this issue in the hippocampal neuronal fields of rats in which long-term potentiation had been induced (Geinisman, DeToledo-Morrell, et al., 1996) as well as of rabbits that had been subjected to eyeblink conditioning (Geinisman et al., in press). The latter study is of particular interest because it examined the consequences of conditioning experienced in vivo. Again, using a stereological quantitative approach (Geinisman, Gundersen, et al., 1996), the two independent studies provided evidence of modification of synaptic shape, but the total number of synapses in the target regions affected by the experimental procedure remained unaltered. The conclusion drawn by the authors was that associative learning is unlikely to involve the formation of new synapses and a net increase in synaptic number, but rather a remodeling of existing synapses. Based on the available literature and on our own extensive database in non-human primates, we are also compelled to conclude that learning and memory in the adult primate cortex are, under normal conditions, likely to be achieved mainly through the strengthening and modification of existing connections rather than by the formation of new ones. This conclusion is in harmony with the general conceptualization of learning and memory as due to the induction of molecular changes, which strengthen the efficacy of existing synapses, as initially postulated by Donald Hebb (1949).

Concurrent synaptogenesis in the cortical mantle

Quantitative description of synaptogenesis in several cortical areas sampled from the same cerebral hemisphere of a series of developing macaque monkeys revealed a remarkably similar course of synaptogenesis during phase 3 in two sensory (visual and somatic), one motor, and one limbic cortical area (Rakic et al., 1986; Granger et al., 1995). Similarly rapid and synchronous accretion of both excitatory and inhibitory synapses have also been found during phase 3 in layer III of the prefrontal cortex of the macaque (Anderson et al., 1995). It has generally been implied, and we also had assumed, based in part on the classical studies of myelin staining in the developing human cerebrum, that the neocortex develops in a distinct hierarchical order, from the sensory to motor to association areas (Flechsig, 1920). Therefore, our initial finding of the concurrent acquisition of synapses in functionally diverse and anatomically separated areas of the cerebrum was unexpected (Rakic et al., 1986). In the past decade, however, additional evidence for concurrent development has been gained from brain imaging studies of the maturation of metabolic activity in the macaque cortical mantle (Jacobs et al., 1995) and the human cerebrum (Chugani, Phelps, and Mazziotta,

1987). Furthermore, quantitative studies of the presence of neurotransmitter receptors in the cortex (Lidow, Goldman-Rakic, and Rakic, 1991; Lidow and Rakic, 1992) also reveal identical profiles of receptor density within the range of human biological variation. Recently, Shankle et al. (1998) reanalyzed the classical cytoarchitectonic studies of Conel and concluded that the differentiation of a variety of morphological and laminar features are remarkably similar across cortical areas, and that developmental patterns in many cortical areas are not distinguishable from one another. Finally, the first two phases of synaptogenesis were also recently found to be synchronous across cortical areas in the human embryo, as they are in the macaque (Zecevic, 1998).

Although the rate of decline to adult levels in phase 4 varies in different areas, this phase of high synaptic density also exhibits an overlap in timing across the cortical regions (Rakic, Bourgeois, and Goldman-Rakic, 1994). We have suggested that this overlap may be essential for competitive interactions and the validation of synaptic connections during experience-dependent development. It should be pointed out that not all evidence is supportive of concurrent synaptogenesis, however. In particular, Huttenlocher and Dabholkar (1997) have reported that during the ascending phase of synaptogenesis in the human brain (phase 3 in macaque), the prefrontal association cortex appears to acquire synaptic junctions more slowly than in the primary visual and auditory cortices. This finding has appeal in its concordance with the general notion that executive functions based on language appear to mature latest in development. We have discussed the technical issues related to this conclusion in considerable detail in several previous publications (Rakic, Bourgeois, and Goldman-Rakic, 1994; Goldman-Rakic, Bourgeois, and Rakic, 1997). At present, neither the sample size (due to scarcity of human tissue) nor the magnitude of the effect is sufficient to challenge the idea of concurrent synaptogenesis.

FUNCTIONAL IMPLICATIONS OF CONCURRENT SYNAPTOGENESIS Studies in human infants show that virtually all cortical functions, including language, have anlage in early infancy and do not arise de novo at a late stage of maturation. In humans, evoked activity in response to the maternal voice is present even before birth (Lecanuet and Granier-Deferre, 1993), and the development of visual acuity and depth perception begins in newborn infants (Teller, 1997, and chapter 6 of this volume). Human infants also evidence expectations based on auditory and visual stimuli that depend on the association cortex. Human infants also show competence to represent numerical entities, including action sequences

(for review, see Wynn, 1998). In the macaque, likewise, early signs of competencies that will later be fully developed are already in evidence. Thus, adult-like properties of neurons in the inferotemporal cortex, such as selective responses to face recognition, are present at only a few weeks after birth (Rodman, Gross, and Scalaidhe, 1993; Rodman, 1994). The critical periods for obtaining social skills and learning simple discriminations also take place as early as two months after birth in macaque infants (Harlow and Harlow, 1962). The cognitive process of working memory, which is subserved by the dorsolateral prefrontal association cortex, likewise emerges in monkeys soon after birth and before the end of phase 3 (Diamond and Goldman-Rakic, 1989), when basic synptoarchitectonic features are still being laid down (Bourgeois, Goldman-Rakic, and Rakic, 1994; Goldman-Rakic, Bourgeois, and Rakic, 1997; Goldman-Rakic, 1987). Although monkeys obviously do not possess language, they do have specializations for working memory processes that are common to all informational domains, and are considered essential for language competence (e.g., Baddeley, 1986; Just and Carpenter, 1992; King and Just, 1991; Miyake, 1994).

Based on our own data and consideration of the literature, we have proposed that the integration of sensory, motor, limbic, and associative areas occurs *pari passu* with the structural development of the cortex as a unified structure, i.e., as “whole cloth” (Goldman-Rakic, Bourgeois, and Rakic, 1997). Further, we would argue that the level and complexity of processing advances with each progressive stage of development. Our working hypothesis is that concurrent synaptogenesis in the whole cortical mantle during the rapid phase 3 allows the early coordinated emergence of all cortical functions (Rakic, Bourgeois, and Goldman-Rakic, 1994; Rakic et al., 1986). In agreement with others, we would argue that concurrency is essential for the competitive and selective interactions among the very heterogeneous cortical inputs arriving at each point of the cortex (e.g., Changeux and Danchin, 1976; Katz and Shatz, 1996; Antonini and Stryker, 1998). However, full maturation of cortical functions is a protracted process that may require many years to be achieved in the macaque (Goldman-Rakic, Bourgeois, and Rakic, 1997) and more than a decade in the human (Rakic, Bourgeois, and Goldman-Rakic, 1994; Huttenlocher and Dabholkar, 1997).

Genetic versus environmental control of synaptogenesis

The onset, the rate, and the concurrent course of synaptogenesis in various areas and layers during its initial

phases occur before birth and are likely to be determined by mechanisms intrinsic and common to the whole cortical mantle (Rakic et al., 1986; Rakic, Bourgeois, and Goldman-Rakic, 1994; Goldman-Rakic, Bourgeois, and Rakic, 1997). We have experimentally tested the independence of these early developmental events from peripheral inputs using several different approaches. In the first approach, we delivered monkeys prematurely three weeks before birth and compared the synaptic density in their visual cortex to that in full-term infants during phase 3 of rapid synaptogenesis. This study showed that premature exposure to a visual environment in preterm infant monkeys neither accelerates nor delays the overall rate of synaptic accretion during the rapid phase 4 in the primary visual cortex (Bourgeois, Jastreboff, and Rakic, 1989). Rather, the rate of synaptogenesis in phase 3 proceeds in relation to the time of conception and not the time of birth or the onset of visual stimulation.

In a second experiment, we enucleated monkeys bilaterally in utero and returned the fetuses to the womb to be delivered by Cesarean section at term (Bourgeois and Rakic, 1996). This study showed that early bilateral enucleation performed before the onset of phase 3 does not alter the mean density of synapses in the visual cortex at the end of this phase or during the plateau phase 4 (Bourgeois and Rakic, 1996). In the enucleated animals the distribution of the major neurotransmitter receptors and cytochrome oxidase patches related to color vision develop normally in spite of the absence of stimulation from the retina during the early prenatal stages (Kuljis and Rakic, 1990; Rakic and Lidow, 1995). In addition, our electron microscopic analysis of the type of synapses in the visual cortex revealed that the proportion of synaptic contacts situated on dendritic spines (75%) and shafts (25%), at the end of phase 3, is not significantly different in enucleated animals compared with normal sighted infants (figures 4.2 and 4.3; see also Bourgeois and Rakic, 1996). However, these proportions, which are normally reversed during infancy (figure 4.3) in the sublayers IVAB and IVC, are not reversed in the enucleates (figure 4.4). Our findings indicate that the onset, time course, and magnitude of cortical synaptogenesis in the primate visual cortex can proceed normally without any visual stimulation or retinal input. On the other hand, we have also provided the only ultrastructural evidence in the primate that the final adjustments in synptoarchitecture, including the proportions of synapses on spines and shafts in thalamorecipient layer IV seem to depend on normal functional input (Bourgeois and Rakic, 1996).

Finally, using a genetic approach, one of us (JPB) has examined a mouse strain bearing a null mutation for the

Otx1 gene, in which the total surface of the cortical mantle is significantly reduced. That is, although all cortical domains are still present in this mutant (Acampora et al., 1996), preliminary data suggest that in the primary visual cortex of this abnormal cortical mantle, the onset and timing of phase 3 of synaptogenesis nevertheless proceed normally in relation to the time of conception (Bourgeois, in preparation).

These quantitative ultrastructural studies indicate that the onset, duration, rate of synapse production, and pattern of synaptogenesis (i.e., the percentages of diverse classes of synapses as a function of postconception age) remain essentially unchanged despite significant developmental perturbations during the first three phases of synaptogenesis, supporting the hypothesis that these phases are determined and coordinated by mechanisms intrinsic and common to the whole cortical mantle. Phases 1 and 2, as well as the first half of phase 3, seem to be dominated by "experience-independent" mechanisms, using the terminology of Greenough and Alcantara (1993). Eventually, the initial intrinsic mechanisms become epigenetically modulated by "experience," i.e., patterned inputs reaching the neocortex from the external world (Bourgeois, 1997). During the second part of phase 3 and plateau phase 4, the mechanisms of synaptogenesis become "experience-expectant" (Greenough and Alcantara, 1993). This means that the presence and repetition of visual, auditory, and other sensory parameters of stimulation and other experience, such as motor activity, become necessary for the proper final adjustment of the cortical circuitry. The transition from intrinsic to extrinsic regulation of synaptogenesis in the cerebral cortex most likely involves the cellular mechanisms underlying learning and memory, which are dealt with in later sections of this volume. Understanding whether learning involves synaptogenesis in adult primates will entail quantitative ultrastructural analysis comparable to that used by Geinisman (in press) in the adult rat.

ACKNOWLEDGMENTS We thank Professor Jean-Pierre Changeux for helpful discussions about the role of genes and epigenesis in formation of synapses. This work was supported initially by the Fogarty International Fellowship, and continuously by the Centre National de la Recherche Scientifique, France (JPB) and U.S. Public Health Service (PGR and PR).

5 Merging Sensory Signals in the Brain: The Development of Multisensory Integration in the Superior Colliculus

BARRY E. STEIN, MARK T. WALLACE, AND TERRENCE R. STANFORD

ABSTRACT During early brain development, systems emerge that are capable of integrating information from different senses. These “multisensory” systems parallel the well-known primary projection systems in which information is segregated on a sense-by-sense basis. The midbrain superior colliculus (SC) is an excellent example of a multisensory system, and recent experiments have shown that its multisensory integration capabilities are not present at birth, but appear gradually during postnatal development. Initially, SC neurons are strictly unimodal and it is not until 12 postnatal days that some of them begin responding to more than a single sensory input. However, it takes several additional weeks before these multisensory neurons are able to integrate their different sensory inputs to enhance or degrade their responses as do their adult counterparts. Among the most significant events that precede the development of this cross-modality integrative ability is the formation of functional inputs from particular regions of the neocortex. It is believed that the timing of this corticotectal development determines the kinds of multisensory information that can be integrated in the SC, and hence the SC-mediated multisensory behaviors that can be expressed at different stages of postnatal development.

All animals are faced with the same daunting task: detecting changes in the external world and interpreting these changes so that they can react appropriately. Their survival depends on it. It is no surprise, then, that the task of accurately representing external “reality” has been a powerful driving force in evolutionary biology and has resulted in animals that possess an impressive array of highly specialized senses. Each of these senses has unique peripheral receptors capable of transducing a specific form of energy into a neural code and a dedicated neural machinery in the central nervous system to represent and interpret these inputs.

By maintaining multiple sensory systems an animal substantially enhances its likelihood of detecting relevant events. These systems not only substitute for one

another when necessary (e.g., hearing can substitute for vision in the dark), but also provide multiple modality-specific “views” that reduce the ambiguity of some signals. For example, two objects or events that cannot be distinguished in one physical dimension (they look alike) may be readily differentiated in another (they feel different). Yet sensory modalities have evolved to work in concert; and although the combination of two dissimilar physical cues, say light and sound, may have little direct effect on each other in the external world, they can profoundly alter each other’s influence on the brain. Thus, the neural consequences of a stimulus in a given modality may depend on which stimuli from other modalities are present at that same moment. That such intersensory interactions have substantial effects on perception and behavior is obvious from the numerous examples in the literature in which an observer’s perception and speed of reaction to one modality-specific stimulus are significantly altered in the presence of another.

At first, such interactions seem surprising. Although some of the sensory modalities may have had similar evolutionary origins (e.g., see Gregory, 1967; Northcutt, 1986), each has become associated with unique subjective attributes, or qualia. These qualia (e.g., hue, pitch, tickle, itch) are inextricably linked to their own sensory systems and have no equivalents in other modalities. Their apparent independence gives the very strong impression that the different sensory systems are also functionally independent—an impression that is quite wrong.

Hosts of perceptual studies demonstrate that stimuli in one modality can significantly alter experiences in another. One broad class of these perceptual effects is called the “ventriloquism effect” (Howard and Templeton, 1966), a phenomenon of intersensory bias in which a stimulus from one sensory modality influences judgments about the location of a stimulus in another modality. The most familiar example, of course, is the situation in which the visual cues associated with the movement of a dummy’s mouth evoke the compelling illusion that

BARRY E. STEIN, MARK T. WALLACE, and TERRENCE R. STANFORD Department of Neurobiology and Anatomy, Wake Forest University School of Medicine, Winston-Salem, N.C.

the sound also originates from the dummy. However, we experience this effect far more commonly while watching a movie or television program. The sounds all originate from the same speakers, and these are comparatively far from the visual images on the screen. Yet each voice seems to originate from the appropriate actor.

There are many other examples of the perceptual effects of cross-modality synthesis (see Stein and Meredith, 1993, and Welch and Warren, 1986, for a more detailed discussion). It should, however, be noted that synthesizing inputs from the same event increases the likelihood that the event will be detected and produce a reaction (Stein et al., 1989). In humans and non-human primates, where eye movements are frequently used as a measure of attentive and orientation reactions, response latencies to a visual or auditory cue can be reduced significantly by presenting both cues simultaneously (Frens, Van Opstal, and Van der Willigen, 1995; Goldring et al., 1996; Hughes et al., 1994; Lee et al., 1991).

Because the sensory environment is constantly in flux, multisensory integration is an ongoing process. Yet, it is a process of which we are completely unaware. Cross-modality phenomena have fascinated observers of human behavior and perception since the time of ancient Greece. While this fascination has led to a wealth of relevant perceptual and behavioral observations, there have been comparatively few corresponding neural studies. The lack of neural data was due, in part, to inherent difficulties involved in assessing the interactions among modalities and linking them to specific perceptual and/or behavioral events, and to placing these observations in a meaningful developmental context.

In recent years, however, the cat superior colliculus (SC) has been used as a model system with which to explore these processes. The choice of this system was based, in large part, on the high incidence of multisensory neurons, and the well-documented involvement of the SC in overt attentive and orientation behaviors (see Stein and Meredith, 1993, for a review). The use of this model affords some intriguing insights into the principles by which individual neurons in the brain synthesize their multiple sensory inputs and how this product may be used to guide behavior. Similar principles operating in other multisensory structures are likely to underlie higher-order cross-modality perceptions. Before discussing how SC neurons develop their multisensory integrative abilities, it is helpful first to examine what is known about this structure and about the principles guiding multisensory integration in mature SC neurons. Because it is the deep layers of the SC that house its multisensory neurons (superficial layer neurons are purely visual) and

the circuitry through which it effects overt responses, it is this division of the structure that will be discussed.

Observations from adult animals

MAP ALIGNMENT The SC—perhaps more so than any other brain structure—functions at the interface of sensory and motor processing. It receives inputs from multiple sensory modalities (i.e., visual, auditory, and somatosensory) and issues motor commands to produce coordinated orienting movements of the eyes, ears, head, and body toward stimuli in each of these modalities. Information about stimulus location is represented topographically within the structure by virtue of an orderly arrangement of neurons according to the location of their respective receptive fields (RFs). The result is a map-like arrangement of the sensory representations wherein the rostral portion of the SC is devoted to representing forward (central) visual and auditory space and the front of the body, whereas peripheral visual and auditory space and the rear body parts are represented in the caudal aspect. Similarly, the inferior-superior axis of sensory space is laid out along the medial-lateral axis of the structure. The spatial register among the different sensory maps is formed, in large part, by multisensory neurons whose different RFs are in register with one another (Stein and Meredith, 1993).

Analogously, the SC contains a “motor map” (Harris, 1980; McHaffie and Stein, 1982; Sparks, 1986; Stein and Clamann, 1981; see also McIlwain, 1991; Roucoux and Crommelinck, 1976) composed of output neurons having “movement fields.” Rather than encoding the position of a sensory stimulus in space, the locus of activity in the motor map encodes a displacement vector, a movement command that reorients the eyes, ears, head, or body a given distance in a particular direction. Given that the goal is to translate a sensory signal into an appropriate motor command, the alignment of the individual sensory maps to each other and to the motor map must surely be a critical factor.

The notion that different sensory modalities access a common motor map dictates the need for mechanisms that establish and maintain spatial registration among modality-specific RFs. Evidence for spatial correspondence among visual, auditory, and somatosensory maps came first from studies of anesthetized animals and has been reported for many species (e.g., see Stein and Meredith, 1993). In these studies, the modality-specific RFs of SC neurons are recorded from animals in which the eyes, ears, head, and body are in alignment. In these circumstances, the coordinate frames of visual (referred to the retina), auditory (referred to the head), and tactile (referred to the body) “space” co-align. Without excep-

tion, these studies suggest close spatial correspondence between RFs representing different modalities. This is particularly evident in individual multisensory neurons. Similar observations have now been made in alert animals whose peripheral sensory organs are aligned (e.g., see Wallace, McHaffie, and Stein, 1997). Considered from a sensorimotor perspective, these findings indicate that when different modality-specific stimuli appear in spatially aligned regions of visual, auditory, or tactile space, they lead to similar spatial distributions of SC activity and, appropriately, specify the same movement vector.

Maintaining map alignment

But what happens when one set of sensory organs is moved relative to the others? As alluded to above, the coordinate systems of visual, auditory, and tactile space use distinctly different referents: Visual space is coded in retinal coordinates, auditory space is coded with respect to the head (and pinnae), and somatosensory space is referred to the body surface. Given that these reference frames can move independently of one another (e.g., when the eyes move but the head remains fixed), there is no unique relationship between a coordinate in one reference frame and that in another. As a result, modality-specific sensory maps in the SC cannot be encoded in their original reference frames (e.g., head-centered, body-centered), if RF registration is to be maintained. For example, eye movements deviate the eyes in the orbit, and each eye movement changes the relationship between the various frames of reference. So, if the eyes are deviated in the orbit 15 degrees to the left, a sensory stimulus 5 degrees to the right of the head would now be 20 degrees right in retinocentric coordinates, but still only 5 degrees right in craniocentric coordinates. If the SC encoded visual information in retinocentric coordinates and auditory information in craniocentric coordinates, a visual and auditory stimulus in the same location in external space would be represented at different loci. Clearly, this would make RF register impossible and make the problem of interfacing with the SC motor map much more complicated.

One possible solution, as discussed by Sparks and colleagues (e.g., Sparks and Nelson, 1987), is that SC sensory maps may be the end-product of coordinate transformations designed to represent modality-specific information in a common frame of reference more closely aligned with the motor representation. In such a scheme, the site of sensory-contingent activity is more closely related to the movement vector required to orient to the stimulus than it is to the spatial location of the stimulus itself. Thus, in the example given above, both

visual- and auditory-evoked activity would produce activation at a site appropriate for producing a 20-degree rightward shift in gaze. Evidence that many SC auditory and somatosensory RFs are, indeed, dynamically remapped (as a function of eye position) to maintain RF alignment has been obtained in both monkeys and cats (Groh and Sparks, 1996; Hartline et al., 1995; Jay and Sparks, 1984; Peck, Baro, and Warder, 1995).

Common coordinates and multisensory integration

Cross-modality topographic register is also critical for the proper synthesis of cross-modality information when multiple sensory cues are available. The multisensory SC neurons that perform this synthesis form a substantial portion of the output pathways of the SC that connect to the brain stem's motor circuitry, and presumably are engaged in premotor signaling (Meredith, Wallace, and Stein, 1992; Wallace, Meredith, and Stein, 1993). As will be shown below, misaligning the different RFs of multisensory neurons substantially alters their integrative products and the behaviors that depend on them.

Operationally, "multisensory integration" is defined as a statistically significant difference between the neuron's response to a stimulus combination compared to its response to the individual component stimuli (Meredith and Stein, 1983). The integration can result in a dramatic increase in the number of impulses evoked above that elicited by the individual stimuli (a "response enhancement" that can exceed the sum of the two modality-specific responses), or a significant decrement below that elicited by either of the individual stimuli (a "response depression" that sometimes eliminates responses altogether). Both effects can be exhibited by the same neuron and depend on a variety of factors, the most obvious of which is the spatial relationship among the stimuli (Meredith and Stein, 1996; Wallace, Wilkinson, and Stein, 1996). When two different sensory stimuli originate from the same spatial location, as when they arise from the same event, they fall within the respective (overlapping) RFs of a given multisensory neuron, and usually yield a substantially enhanced response. If, however, the stimuli are spatially disparate (e.g., causally unrelated), so that one stimulus originates from a location outside its modality-specific excitatory RF, no enhancement of the response to the other stimulus occurs. And, if that stimulus falls within the inhibitory region of its RF, it will depress (and may eliminate) responses to the other (Kadunce et al., 1997). Note that response enhancement could serve to facilitate orienting responses to a particular spatial location, whereas response depression suggests the existence of competitive interactions

FIGURE 5.1 Enhancement of multisensory attentive/orientation behaviors to spatially coincident visual and auditory stimuli. Top: Animals are trained and tested in a perimetry device in which visual (LED) and auditory (speaker) stimuli are spaced at regular intervals. Animals were rewarded with a food pellet for correctly approaching the active stimulus site. Trials began with the cat fixated on the central LED. In this paradigm, visual, auditory, and spatially coincident visual-auditory (VA) stimuli were delivered in an interleaved manner and the percentage of correct responses was scored. Bottom: Data show that at all locations, behavioral responses to the spatially coincident visual-auditory combination were strongly enhanced when compared with the responses to either of the stimuli presented alone. (From Stein et al., 1989.)

designed to prevent the simultaneous representation of more than one movement goal within the SC (figure 5.1).

Other factors governing multisensory integration

The magnitude of a response enhancement can also vary depending on the timing of the stimuli. Studies in which the onset asynchronies of two stimuli are manipulated have shown that there is a surprisingly long period after one stimulus is presented during which an interaction with another stimulus is possible. Although some visual-auditory neurons exhibit their greatest enhancements when both stimuli occur simultaneously, others prefer an onset asynchrony of 50 ms or more (with the visual stimulus leading the auditory). Generally, there is a progressive decrease in the magnitude of the interaction as the onset asynchrony increases or decreases from the optimum (Meredith, Nemitz, and Stein, 1987; Wallace, Wilkinson, and Stein, 1996; Wallace and Stein, 1997a).

The magnitude of a multisensory enhancement also varies significantly depending on the level of effectiveness of the unimodal stimuli being combined. This relationship is an inverse one. Hence, the combination of weakly effective unimodal stimuli results in the greatest proportionate response enhancement, whereas combinations of very effective unimodal stimuli produce response enhancements that are proportionately quite small. These observations emphasize that the usefulness of multisensory enhancement in the SC is greatest when the intensity of the initiating event is weakest. This makes intuitive sense, as highly effective stimuli already produce strong signals in the central nervous system. Consequently, their detection and likelihood of evoking overt behaviors are already high.

It might seem reasonable to suppose that as long as a neuron receives inputs from multiple sensory modalities, it will integrate those inputs and show the characteristic multisensory enhancement (or depression) described above. However, this is not the case. SC neurons appear to require specific inputs in order to produce these cross-modality integrative products. The most important of these come from an area of cortex, the anterior ectosylvian sulcus (AES).

The AES is a corticotectal (Stein, Spencer, and Edwards, 1983) "association" area composed of visual (AEV; see Mucke et al., 1982; Olson and Graybiel, 1987), auditory (field AES, or "FAES"; see Clarey and Irvine, 1990), and somatosensory (SIV; see Clemo and Stein, 1982) regions. Multisensory neurons in the SC receive convergent inputs from unimodal cells in these different subregions (figure 5.2; see Wallace, Meredith, and Stein, 1993), as well as from unimodal ascending pathways (for a review, see Edwards et al., 1979). Thus, a visual-auditory SC neuron may receive ascending inputs from the retina and inferior colliculus and descending inputs from the AEV and FAES subdivisions of the AES. Yet, the inputs from AES are quite special, and their elimination produces remarkably specific effects on the great majority of multisensory SC neurons that have been examined: Their unimodal responses may be only modestly affected, but their capacity to engage in multisensory integration can be markedly suppressed (Wallace and Stein, 1994). The suppression of multisensory integration is such that even the seemingly straightforward addition of the responses normally evoked by the two unimodal stimuli is lost (figure 5.3). Apparently, then, additive (and even subadditive) multisensory enhancement is not as straightforward as it might first appear; and regardless of magnitude, the multisensory enhancement produced by coupling two unimodal stimuli is generally dependent on integrative mechanisms facilitated by corticotectal influences.

Visual-Somatosensory

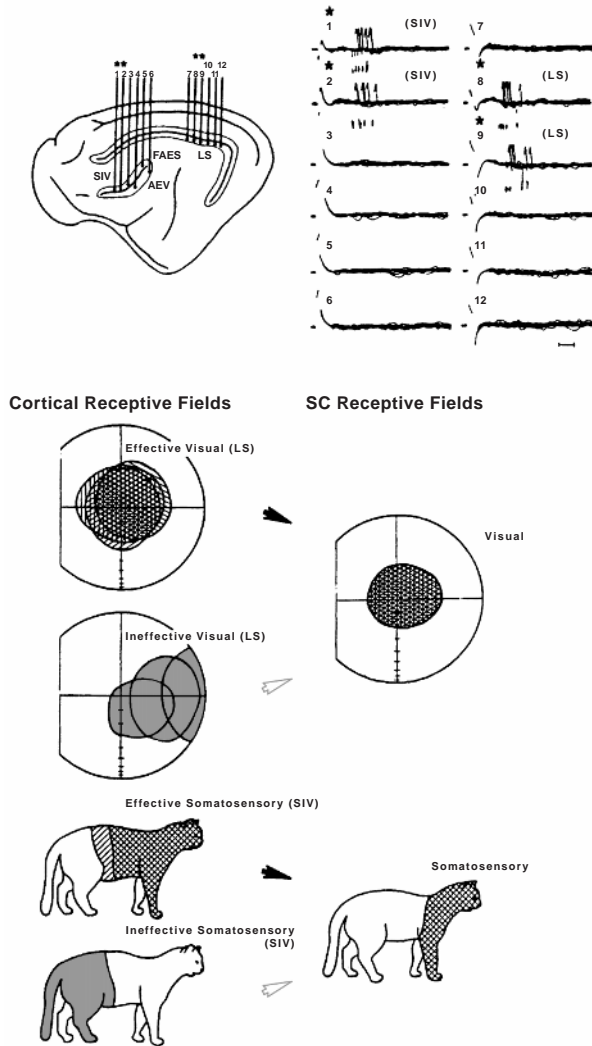

FIGURE 5.2 Visual and somatosensory cortical inputs converge on an individual SC neuron. Top: Electrode implantation sites in cortex are shown on the left and the evoked activity of a multisensory SC neuron is shown on the right. Note that stimulation of sites in somatosensory (SIV) and visual (LS) cortices orthodromically activated this visual-somatosensory SC neuron, whereas stimulation in auditory (FAES) cortex was ineffective. Bottom: The effective cortical stimulation sites also had multiunit receptive fields that were well matched with the receptive fields of the activated SC neuron. (From Wallace, Meredith, and Stein, 1993.)

The specificity of the corticotectal influences from AES on multisensory integration was quite unexpected. It turns out that what has been considered, in classical terminology, an area of “association cortex” does, indeed, associate among the senses, but does so through a connection to a subcortical structure very far away. In this manner AES not only controls multisensory integration in the SC, but also exerts substantial influence on the attentive and orientation functions the SC mediates.

This became particularly evident from a parallel study using behavioral techniques.

Cats were first trained in a perimetry device to orient to a visual stimulus. In some instances they were taught to orient to an auditory stimulus, in others they were taught to ignore it, and in still others the auditory stimulus was neutral (some animals were trained and tested in all paradigms sequentially). Regardless of the training paradigm, or the area of sensory space examined, the results obtained were substantially the same. When visual and auditory cues were presented together in time and space, there was a significant enhancement in correct responding that exceeded statistical predictions based on combining response probabilities to the unimodal stimuli (figure 5.4). When the cues were spatially disparate, correct responding was markedly decreased (Stein et al., 1989). However, when a broad region of the AES was temporarily deactivated (both AEV and FAES were affected), both the salutary effects of spatially coincident combinations of cross-modality stimuli and the inhibitory effects of spatially disparate cross-modality stimuli were profoundly degraded without affecting unimodal behaviors (Wilkinson, Meredith, and Stein, 1996). Often there were no significant differences between the response probabilities to a visual cue alone and the visual-auditory stimulus combinations.

Developing multisensory processes

An issue that has been of considerable interest to neuroscientists for some time now is whether the newborn brain is capable of engaging in this sort of cross-modality integration or if this capability appears only after extensive postnatal experience with these (or similar) cues. Of some relevance to the development of current thought regarding this issue are discussions in the perceptual literature, particularly those related to a syndrome called “synesthesia.” Individuals with synesthesia have sensory experiences that may seem strange to most of us. A modality-specific stimulus can trigger an entire complex of impressions that cross sensory boundaries. For example, a particular sound may trigger a specific visual impression, a well-characterized tactile experience, or even a distinct taste. The term itself means “joining the senses,” and investigators have compiled and described a fascinating array of synesthetic experiences (see Cytowic, 1989; Marks, 1975). Although the neural mechanisms underlying this syndrome remain unknown, new imaging studies in synesthetes show great promise in identifying the brain regions that become active during synesthetic experiences (e.g., Paulesu et al., 1995).

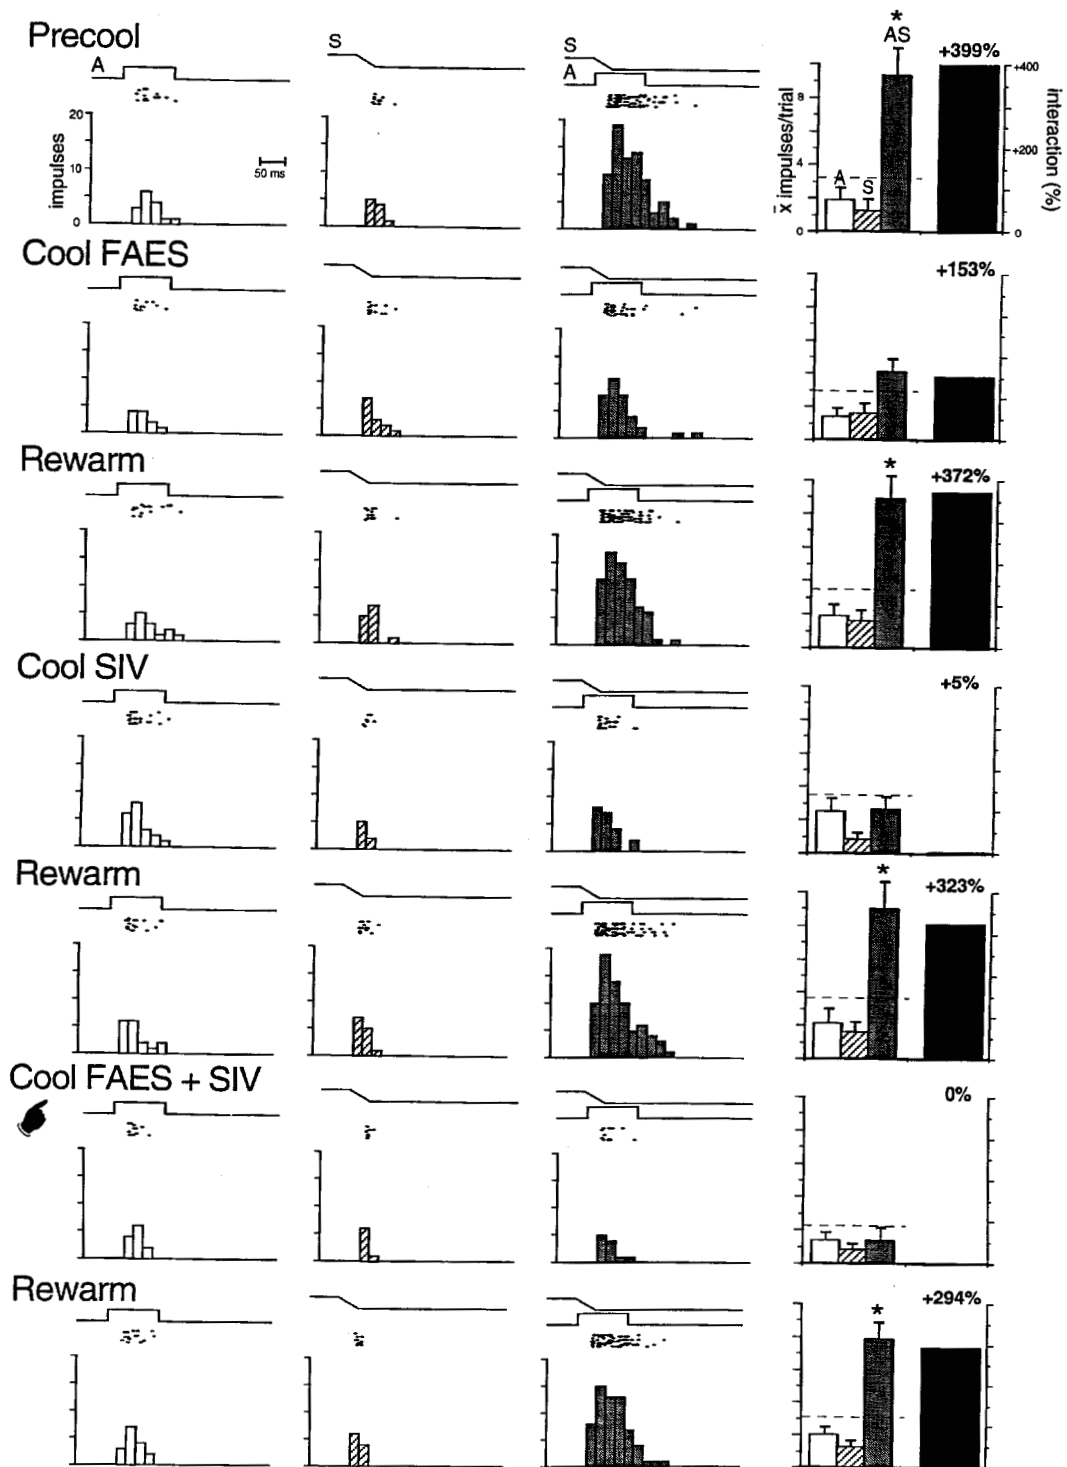

FIGURE 5.3 AES deactivation abolishes SC multisensory integration. Rasters, peristimulus time histograms, and summary bar graphs depict the responses of this auditory-somatosensory SC neuron under various conditions. The top panel (precool) shows the control responses of this neuron to: the auditory stimulus alone (left; the square wave represents the stimulus and is labeled A), the somatosensory stimulus alone (ramp labeled S), and the auditory-somatosensory (AS) stimulus combination. The summary bar graph shows that the response to the stimulus com-

bination was enhanced far above that to either stimulus alone, and well above the sum of the two unimodal stimuli (dashed line). Note that when the auditory (FAES) and somatosensory (SIV) divisions of AES cortex were deactivated by cooling, response enhancement was degraded. During rewarming trials the normal levels of enhancement were reinstated. When both FAES and SIV were deactivated, multisensory enhancement was abolished, even though unimodal auditory and somatosensory responses remained. (From Wallace and Stein, 1994.)

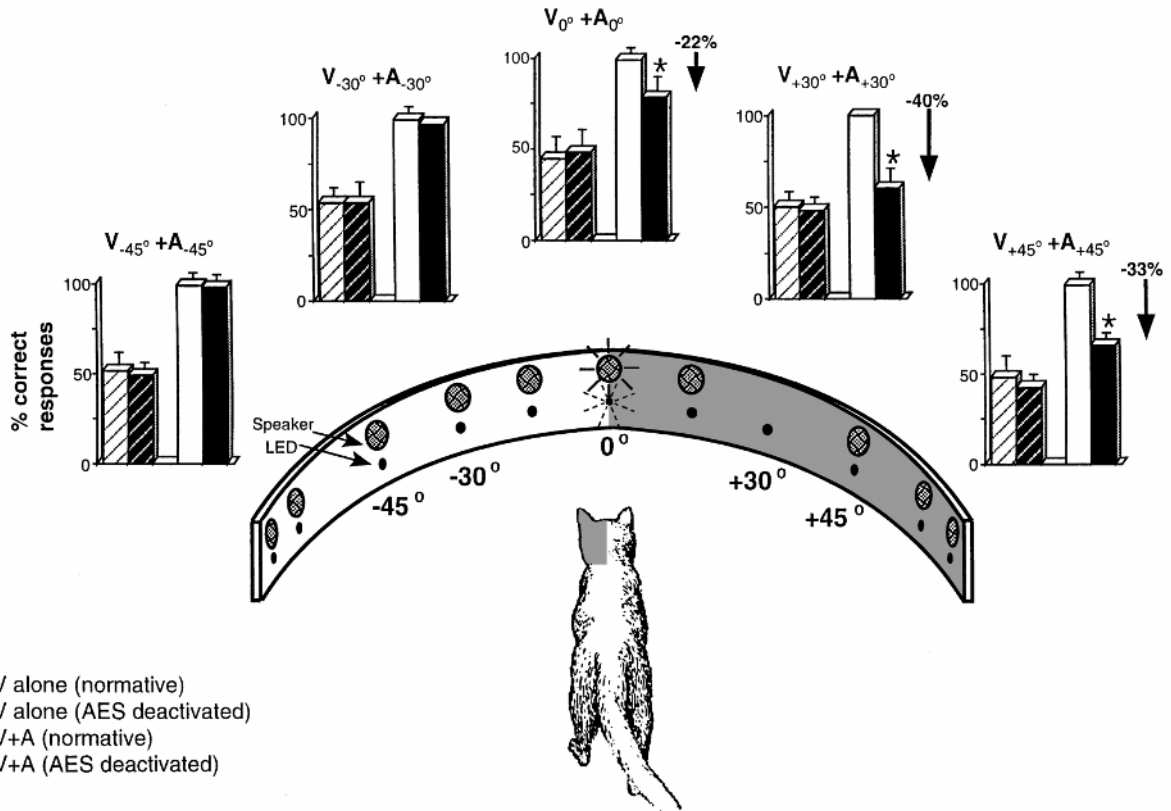

FIGURE 5.4 Deactivating AES impairs multisensory attentive/orientation behaviors. The behavioral paradigm is the same as that described in figure 13.1. The bar graphs above the perimeter display the percentage of correct responses to the visual stimulus alone and the spatially coincident visual-auditory stimulus combination, under both normative and AES deactivation conditions (deactivation was accomplished via lidocaine delivered through indwelling cannulae implanted in AES). Responses were examined to stimuli at five spatial locations. During testing, the intensity of the visual stimulus (LED) was ad-

justed so that the animal approached the correct location on approximately 50% of the unimodal trials. However, pairing this visual stimulus with a spatially coincident auditory stimuli resulted in near-perfect scores at all locations. When AES was deactivated, orientation to contralateral multisensory stimuli was disrupted, even though responses to the contralateral unimodal visual stimulus were unaffected. The percentage of correct responses to all ipsilateral stimuli was also unchanged. The shading depicts the deactivated hemisphere and the region of space affected. $p < .05$. (From Wilkinson, Meredith, and Stein, 1996.)

Yet regardless of the critical sites involved in the syndrome, some researchers believe that synesthetic experiences are the norm in neonates, becoming degraded with maturation and sensory experience. These researchers believe that sensory impressions form a “primitive unity” at birth (see Bower, 1977; Gibson, 1966; Ryan, 1940; von Hornbostel, 1938), so that a modality-specific stimulus can produce “. . . sensations [that] spill from one sensory system into another” (Maurer and Maurer, 1988). This presupposes that many intersensory phenomena are inborn. Not all investigators accept this idea; many contend, as did Piaget and von Helmholtz, that the sensory modalities are already well-differentiated from one another at birth and that associations

among them must be learned (e.g., see Piaget, 1952; von Helmholtz, 1884/1968). This would lead one to expect that intersensory processes develop only gradually with learning and/or experience. This latter “epigenetic” view may seem the more conservative of the two; however, many observations do not fit easily within established learning paradigms, or are inconsistent with a gradual acquisition of intersensory capabilities (see also Lewkowicz and Lickliter, 1994). One of the most provocative of these was described by Meltzoff and his colleagues (e.g., Meltzoff and Moore, 1983a,b), who showed that within minutes of birth, human babies could imitate the facial expressions of the investigator. When the investigator opened his mouth, the baby

opened its mouth; when the investigator stuck out his tongue at the baby, the baby returned the favor. Obviously, the infants had little chance to learn these apparent cross-modality associations, yet they appeared to be matching what they saw to what they felt, a process that Meltzoff called “active intermodal mapping.”

For some, this issue remains a contentious one. But regardless of whether or not the newborn brain is capable of sophisticated forms of intersensory experience, multisensory integration, and/or cross-modal transfer, little doubt remains that modality-specific experiences during early life can have an impact on the later use of other modalities. This is evident from experiments in which patterned vision has been induced earlier than normal, either by surgically opening the eyelids in very young mammals or by making small openings in eggs so that bird embryos can receive patterned visual stimuli (Gottlieb, Tomlinson, and Radell, 1989). These earlier-than-normal visual experiences disrupt the normal postnatal auditory dominance and even interfere with the tendency to exhibit normal preferences for species-specific sounds. Similarly, early postnatal experience with nonlocalized auditory cues can interfere with later use of spatially restricted auditory cues (see Lickliter and Banker, 1994), and the lack of coincident auditory-visual experience disrupts normal intersensory development (Lickliter, Lewkowicz, and Columbus, 1996).

Early sensory experiences may even help determine which sensory convergence patterns survive in the brain (Rauschecker, 1996). Exuberant connections that cross modality-specific boundaries have been demonstrated in the cortex in newborn rodents and carnivores. Many of these inputs are “inappropriate” (e.g., visual inputs to auditory or somatosensory structures) as they are not maintained into adulthood. Their transience is believed to be a consequence of their competitive disadvantage with other inputs, but they can be retained if these other inputs are disrupted (Frost, 1984; Innocenti and Clarke, 1984; Sur, Garraghty, and Roe, 1988).

In altricial mammals like the cat, the brain requires a great deal of postnatal maturation before it can underlie adult-like behaviors. The minimal sensory and sensorimotor capabilities of the neonatal kitten reflect an immaturity of many CNS structures, including the SC, affording little hint of the impressive skills it will develop later. It seems hopelessly inept. However, from the perspective of the investigator, the gradual postnatal development of the cat SC provides an opportunity to examine how its neurons develop their sensory responses and especially their striking ability to synthesize cross-modality cues. Thus, the discussion below makes primary use of the cat model, and, unless otherwise stated, the data described below refer to this species.

The immaturity of the newborn cat SC is evident in its paucity of electrical activity. Few of its neurons exhibit spontaneous activity, and fewer still are responsive to sensory stimuli. However, as if to prepare the animal for its most immediate postnatal task of nuzzling its mother in search of milk, at least some tactile-responsive neurons in the SC (and other somatosensory structures) become active in late fetal stages (Stein, Labos, and Kruger, 1973a). The ability to distinguish perioral tactile cues is critical for the kitten to find the nipple and get it into its mouth (Larson and Stein, 1984). These early sensory-responsive SC neurons have weak responses that fatigue quite readily during the first few postnatal days. From a functional perspective, the structure is purely unimodal (i.e., somatosensory) at this time. It is not until about 5 dpn that neurons responsive to auditory cues appear (though none of these neurons are multisensory), and the first deep-layer visual neurons are not active until about 3 weeks postnatal (visual neurons in the purely visual superficial layers are active at 6–7 dpn; see Kao et al., 1994; Stein, Labos, and Kruger, 1973a,b; Wallace and Stein, 1997a).

These neonatal neurons do not yet receive descending (i.e., cortical) inputs; therefore their response properties reflect only ascending and intrinsic influences (Wallace and Stein, 1997a; Stein and Gallagher, 1981). The RFs of early SC neurons are extremely large, whether they are unimodal or multisensory. Visual RFs cover much of the contralateral visual field and somatosensory RFs cover most of the contralateral body. Auditory RFs are completely unformed (i.e., omnidirectional), so that responses are evoked to stimuli anywhere in space. As postnatal maturation proceeds, there is a progressive shrinking of RFs until the characteristic adult-like tuning

FIGURE 5.5 The incidence of multisensory SC neurons increases during the first 3–4 postnatal months. Plotted is the proportion of multisensory neurons (as a percentage of all sensory-responsive SC neurons) as a function of postnatal age. (From Wallace and Stein, 1997)

FIGURE 5.6 Eye movements can be evoked via electrical stimulation of the SC prior to the appearance of visual responses. The data shown are taken from a 2-day-old cat in which electrodes were placed in the left (penetration 1) and

right (penetration 2) SC. Stimulation at these sites evoked conjugate contralateral eye movements. The direction of movement and excursion length are depicted by the arrows. (From Stein, Clamann, and Goldberg, 1980.)

and topographic alignment among the RFs of multisensory neurons (and among the maps) become evident (Wallace, Meredith, and Stein, 1993; Wallace and Stein, 1996; Wallace and Stein, 1997a,b). A similar developmental contraction of RFs has been noted in monkey (Wallace, McHaffie, and Stein, 1997), ferret (King et al., 1996), owl (Brainard and Knudsen, 1995), and mouse (Benedetti, 1991). If similar mechanisms are operative during human development, it might help explain observations that the spatial concordance of visual and auditory stimuli becomes increasingly important to infants as they age (Morronegiello, 1994).

The functional ontogeny of multisensory neurons in cat SC parallels that of their unimodal counterparts, with the first being auditory-somatosensory neurons that appear at 12 dpn, while visual multisensory (including trimodal) neurons do not appear until about 3 postnatal weeks. However, achieving the adult-like number of multisensory neurons is a very gradual developmental process that is not completed until about

12 postnatal weeks (figure 5.5; see Wallace and Stein, 1997a).

Very little is known about the maturation of the motor or sensorimotor aspects of the SC. Some eye movements can be effected via direct electrical stimulation of the SC as early as 2 days postnatal (figure 5.6), before its neurons are visually responsive; but the thresholds for evoking these movements are quite high, and only few sites are effective. As noted above, visually responsive neurons do not appear until 6–7 dpn in the superficial layers, and not until much later in the deeper layers of the SC, in keeping with the late maturation of visually guided behaviors (Fox, 1970; Norton, 1974). Interestingly, the electrically evoked movements from the neonatal SC show at least the rudiments of adult-like topography, suggesting that premotor connections are being established even before sensory inputs are present. Specifically, in neonatal kittens, stimulating in the left SC moves the two eyes rightward, and stimulation of the homotopic site in the opposite SC produces a

a**b****c****d**

mirror-image leftward eye movement, just as in the adult (Stein, Clamann, and Goldberg, 1980; Stein, Goldberg, and Clamann, 1976).

Maturation of cross-modality receptive field alignment

By the end of the second postnatal month, neurons in the cat SC appear to have properties very much like those found in the adult. Natural sensory stimuli evoke vigorous responses, the animal engages in rapid orienting movements to novel stimuli, and appropriately directed movements can be evoked easily by electrical stimulation of the structure (see Norton, 1974; Stein, 1984; Stein, Clamann, and Goldberg, 1980; Stein, Labos, and Kruger, 1973a,b; Wallace and Stein, 1996; Wallace and Stein, 1997a). Furthermore, the sensory (and motor) maps have established their close topographic register as individual RFs decline in size with development (figure 5.7). The development of the alignment among the various sensory maps, which are constructed from spatially matched ascending and descending projections in each modality, has already been shown to be essential for SC neurons to engage in meaningful multisensory integration (see Wallace, Meredith, and Stein, 1993; Wallace and Stein, 1994, 1997a), and active processes ensure that the different sensory maps align with one another (Benedetti, 1995; King and Carlile, 1993; Knudsen and Brainard, 1991). Presumably, this is because the alignment of sensory maps, and especially the alignment of RFs in multisensory neurons, has substantial adaptive value. As discussed earlier, the spatial alignment among a given neuron's modality-specific RFs is critical to the production of response enhancement to spatially coincident stimuli and response depression to spatially discordant stimuli. These physiological effects, in turn, enhance the salience of related or meaningful events and degrade the salience of unrelated events—with the obvious parallels in the likelihood of generating an overt response (Stein et al., 1989; Wilkinson, Meredith, and Stein, 1996).

FIGURE 5.7 Receptive field size declines with development. (a) Plot of receptive field size as a function of postnatal age for each modality of SC multisensory neurons. (b) Receptive fields (shading) of visual-auditory neurons at three representative developmental stages. Note the decline in size and the increasingly apparent spatial register of receptive fields with age. Each concentric circle represents 10°. In the convention for auditory space, caudal space is depicted by the semicircular “wings,” which have been split and folded forward. (c) Receptive fields of auditory-somatosensory neurons at three ages. (d) Receptive fields of visual-somatosensory neurons at three ages. (From Wallace and Stein, 1997.)

Current thinking is that the development of the refined auditory map that characterizes the normal adult requires early visual-auditory experience. This conclusion is based on the data from experiments in which visual or auditory inputs are manipulated during development. For example, some experiments have been conducted in which animals are raised with a sound-attenuating plug in one ear. This renders the inputs from that ear substantially less effective in driving central auditory neurons than those from the open ear and disrupts the normal balance of binaural cues used to construct a computational map of auditory space in the SC (i.e., interaural level difference). Yet the auditory map that is formed looks surprisingly like the one found in normal animals, and is in excellent register with the visual map (figure 5.8; see King et al., 1988; Knudsen, 1983). The alignment of visual and auditory RFs in individual multisensory neurons is also excellent. Apparently, the brain is able to compensate for the imbalance between the two ears by changing their relative influence on SC neurons. In order to do so, it is believed to use the visual map as a template, or comparator, with which to calculate how much it must alter the timing and/or weight of the inputs from each ear to produce a matching map of auditory space. Powerful evidence for this idea also comes from studies in which the visual axis is shifted relative to the auditory axis either by placing prisms on the eyes or surgically shortening the extraocular muscles so that the eyes themselves are deviated. Under such conditions, a seemingly normal visual-auditory register develops because the auditory axis shifts to accommodate the change in the visual axis (King et al., 1988; Knudsen and Knudsen, 1989). Presumably, coincident visual and auditory experiences derived from discrete cues that are closely linked to one another are essential for the precision of intermap calibration both in normal animals and in animals with altered visual experience. Thus, eliminating the opportunity for such experience during development (e.g., dark rearing, omnidirectional sound rearing) prevents the formation of a precise auditory map and precise intermap register (Withington-Wray, Binns, and Keating, 1990a; Withington-Wray et al., 1990b).

But where is this visual template that is used to align the auditory map? The most obvious visual referent is the deep-layer visual map. After all, a significant component of this map is derived from visual-auditory neurons, and the substantial visual-auditory interactions in deep-layer neurons have been the subject of much of this chapter. A complication, however, is that the auditory responses of SC neurons develop much earlier than their visual responses. Furthermore, the omnidirectional early auditory “receptive fields” already have contracted significantly before functional visual inputs are

FIGURE 5.8 The auditory map in the ferret SC develops even in animals raised without normal binaural inputs. Data are plotted both for normal animals and for those in which one ear was plugged prior to the onset of hearing. In both populations,

there were similar systematic and covarying shifts in the visual and auditory receptive fields at different locations in the SC. (From King et al., 1988.)

demonstrable in deep-layer neurons (Wallace and Stein, 1997a); and even after visual inputs can drive these neurons, it is quite some time before there is any evidence of visual-auditory interactions (Wallace and Stein, 1997a)—an issue that will be discussed in detail in the next section. Such observations offer no support for the hypothesis that the visual template is in the multisensory layers of the SC. Yet, neither are they confutative. A crude auditory map can develop in the absence of visual input, making a visual referent unnecessary for the initial contraction of auditory RFs. Thus, it may be that only the later refinement in auditory RFs is dependent on coincident visual inputs (e.g., see King and Carlile, 1993; Knudsen, Esterly, and du Lac, 1991).

While there is a good deal of face validity to the postulate that the deep-layer visual map is the template for the formation of an auditory map, there is also reason to suspect that the visual template resides in the superficial layers of the SC. This overlying and purely visual region develops visually responsive neurons at 6–7 days postnatal (Stein, Labos, and Kruger, 1973a), and their RFs are already organized into a well-defined map of visual space at 8–10 days postnatal (Kao et al., 1994; also see Wallace, McHaffie, and Stein, 1997), which is long before the auditory map is organized. Furthermore, vertically oriented superficial-deep layer visual connections have been demonstrated in a variety of species, including the cat (Behan and Appell, 1992; Mooney et al., 1988), and partial lesions of the superficial layers in neonatal ferrets produce a disorganized auditory map just below the lesion site (King et al., 1996). Further evidence

for a role for the superficial visual map in the development of deep-layer auditory topography comes from studies in which chronic application of the NMDA receptor antagonist MK801 to the superficial SC layers disrupts the development of the auditory space map (Schnupp et al., 1995).

Clearly, many issues have yet to be fully resolved regarding the development of multimodal RF properties. Indeed, some of the issues may be even more complex than apparent from the discussion thus far. For example, while the majority of studies provide evidence that a visual referent is used to calibrate computationally derived auditory maps, there is evidence in mouse to suggest that visual and auditory maps are adjusted to compensate for altered tactile experience. In one experiment, Benedetti (1995) bent the left vibrissae into the right hemifield, thereby disrupting the normal correspondences among visual, auditory, and tactile cues. Remarkably, in animals subjected to the altered experience from birth, the visual RFs that normally would have represented vibrissae-related regions in the left hemifield were found to be shifted to represent regions in right visual space. Taken together with the observations made in other species, the data suggest that the relative ecological importance of a sensory modality may be a critical factor in determining which sensory map serves as the referent to the others. It might be argued that, unlike the cat or owl, the mouse places more “value” on tactile than on either visual or auditory information, hence the use of a somatosensory rather than a visual or auditory referent for SC map construction. Even in species in

which somatosensation is not the “dominant” modality, tactile input has been shown to influence the spatial organization of visual information in cortex (see Fogassi et al., 1996; Graziano, Hu, and Gross, 1997).

Regardless of which modality serves as the mapping template, the establishment of sensory map registration ensures a consistent, modality-independent relationship among the sensory maps and between the sensory and motor maps in the SC. Although much is known about the generation and maintenance of sensory map register, we know very little about the developmental sequences that lead to topographic register between the sensory and motor maps. Most likely, the recalibration of motor output following altered sensory input (e.g., via prisms or vibrissal deformation) requires a flexible linkage between sensory and motor topographies, a linkage that is adaptable only as a consequence of sensorimotor behavioral experience. Dynamic processes also must play a role in calibrating the mechanisms that maintain map alignment during normal behavior. Such calibrations must make use of proprioceptive or efference copy information to effect the coordinate transformations necessary to maintain map alignment despite changes in the relative position of the eyes, ears, head, and body.

Maturation of multisensory integration

One might reasonably postulate that at the point at which an individual SC neuron develops the ability to respond to inputs from different modalities (i.e., becomes multisensory), it would also exhibit the ability to integrate them. However, this postulate proved to be incorrect. In both cat (Wallace and Stein, 1997a) and monkey (Wallace, McHaffie, and Stein, 1997), the youngest multisensory neurons are unable to integrate their different sensory inputs to produce the response enhancement or depression that characterizes adult multisensory integration (figure 5.9). Their responses to the combination of two different sensory cues generally do not differ substantially when one or the other cue is presented individually. Presumably, these neonatal multisensory responses reflect the absence of functional corticotectal inputs. At this stage, then, the neonate might represent the developmental counterpart of an adult animal whose AES has been deactivated. Several weeks later the situation has changed dramatically, with multisensory neurons exhibiting adult-like interactions, presumably reflecting the maturation of the essential corticotectal circuits (figure 5.10).

The observation that the multisensory properties of the SC develop only gradually in postnatal life contrasts with expectations based on the idea of a “primitive

FIGURE 5.9 SC neurons in young cats do not exhibit multisensory enhancement. In this example of a visual-somatosensory neuron in a 20-day-old cat, the combination of visual and somatosensory cues resulted in a response that was neither better nor worse than the response to either of the unimodal stimuli. (From Wallace and Stein, 1997.)

unity” among the senses. However, the sequential appearance of somatosensory, auditory, then visual responses in this structure (see Stein, Labos, and Kruger, 1973a,b; Wallace and Stein, 1997a) is consistent with the idea of a temporal window during which the fundamental organization and information-processing capabilities of one sensory modality are developed before repeating this process for another, and before dealing with the most complicated task of integrating their different signals (see Turkewitz and Kenny, 1985 for a discussion of the possible adaptive significance of sequential sensory development). However, it remains to be seen whether the developmental profile so apparent in the cat SC is also present in other CNS structures and other species.

Concluding remarks

William James (1890) described our initial impression of the world as a “blooming, buzzing confusion” of sensory stimuli—a description implying that it is only after we are

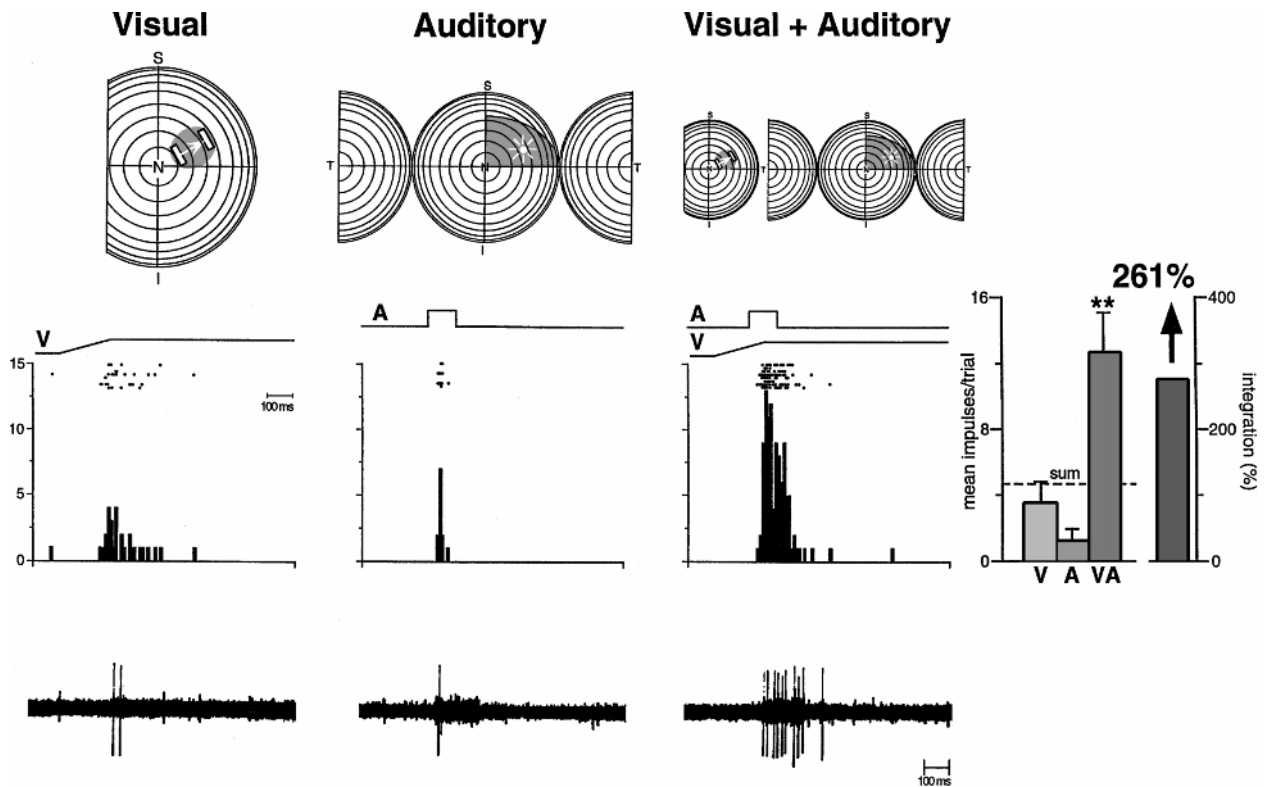

FIGURE 5.10 As soon as they develop the capacity for multisensory integration, neonatal SC neurons look like their adult counterparts. Receptive fields for this visual-auditory neuron in a 30-day-old animal are shown at top. Rasters, histograms,

oscillographs, and summary bar graphs show the strongly enhanced responses of this neuron to the visual-auditory combination. Conventions are the same as in figure 13.3. (From Wallace and Stein, 1997.)

able to sort among stimuli, relating them to one another and to specific consequences, that we begin to learn about our world. It is interesting to note, however, that the experience of using the senses to do just that is an important determinant of their ultimate organization and functional capability. In the current context the experience of coordinating information from different senses has been shown to play an essential role in aligning and calibrating multisensory SC RFs and in the representation of auditory space.

Although it seems reasonable to suppose that the impact of specific cues, and perhaps even the magnitude and sign of an interaction in multisensory neurons, also depends on the frequency and consequences of early stimulus pairings, we really know very little about these issues. Nevertheless, at this point it seems most likely that the effects of early experience operate within the framework of the spatial and temporal principles that have already been shown to govern SC multisensory integration in normal adult animals. Based on data from experiments in polysensory cortex (see Jiang et al., 1994; Ramachandran et al., 1993; Wallace, Wilkinson, and Stein, 1996), at least some of these principles appear to be general features of multisensory structures (though they must surely have very different impacts on behav-

ior and perception). Employing similar principles of multisensory integration at different levels of the neuraxis is a parsimonious way to increase or decrease the salience of the same stimulus complex. It is also an effective way to link SC-mediated immediate behaviors with the “higher” perceptual and cognitive processes that coincide with these behaviors and provide conscious dimension to the experience.

6 Visual Development: Psychophysics, Neural Substrates, and Causal Stories

DAVIDA Y. TELLER

ABSTRACT This chapter addresses the development of vision in human and monkey infants, as well as the complexities of explaining the development of visual function on the basis of anatomical and physiological development of the visual system. The literature on the development of several visual functions—grating acuity, critical flicker frequency, stereoacuity, vernier acuity, and spatial and temporal contrast sensitivity functions—is selectively reviewed. A distinction is introduced between a *critical locus*—a neural stage at which information is importantly transformed in adults—and a *critical immaturity*—a neural stage at which the visual capacity of the infant is importantly reduced below that of the adult; and it is argued that critical immaturities need not be confined to critical loci. Examples of current theoretical accounts of visual development are discussed from this perspective.

The goals of visual neuroscience are threefold: to describe what and how well we see; to describe the characteristics of the neural substrate that make seeing possible; and to explain the characteristics of vision on the basis of the characteristics of its neural substrate. The goals of developmental visual neuroscience are similarly threefold: to establish the time course of emergence of the various visual functions; to explore the developmental time course of elements of the neural substrate; and to explain the development of vision on the basis of the development of its neural substrate. Visual neuroscience and visual development are arguably among the most advanced of the disciplines that make up the cognitive and developmental behavioral neurosciences, and it is hoped that some of the successes in the visual realm can provide useful precedents for work in related fields.

The current chapter offers a brief progress report on the strategies and accomplishments of developmental visual neuroscience. The first section introduces techniques for testing vision in human and monkey infants, and shows the parallel emergence of grating acuity in both species. In the next two sections, the development of several additional visual functions is described. Finally, these data are compared with selected anatomical and physiological data on development of the visual sys-

tem in infant primates, and some current models of visual development are briefly analyzed. More extensive reviews can be found elsewhere (Movshon and Kiorpes, 1993; Simons, 1993; Teller, 1997, 1998; Vital-Durand, Atkinson, and Braddick, 1996).

Behavioral techniques and a monkey model

The most common technique used for testing the development of visual function is forced-choice preferential looking, or FPL (Teller, 1979). The FPL technique is based on the infant's propensity to stare at boldly patterned objects. Briefly, the infant is held in front of a visual display. To test grating acuity, squarewave gratings—sets of black and white stripes of various spatial frequencies—are presented randomly on either the right or the left side of the display in a series of trials. An observer who cannot see the stimuli observes the infant via a peephole or a video monitor. On each trial the observer must use the infant's staring behavior to judge the left-right location of the grating. The finest grating for which the observer can do better than chance at judging the location of the grating is taken as the estimate of the infant's acuity. For older ages, operant reinforcers are added. The combination of FPL and operant techniques yields reliable data at all ages throughout infancy, up to the ages at which adult psychophysical measures can be used.

Our approach to establishing the validity of infant monkeys as an animal model for human visual development has been to collect developmental data with similar stimuli and techniques from both species. If the two species have similar visual capacities and go through similar sequences of developmental change, albeit on different time scales, it should be possible to establish an age conversion factor between the two species. Such an age conversion allows one to generalize the results of invasive work on the monkey infant to the human infant, and use the invasive data taken on the monkey to model human visual development.

Early studies showed that human and pigtail macaque monkey infants could be tested with similar behavioral

FIGURE 6.1 The development of forced-choice preferential looking (FPL) acuity (closed circles) and operant acuity (closed triangles) in human infants (left) and pigtail macaque infants (right). Human age is plotted in months, and monkey age in weeks. Both species show similar acuity values near birth. Acuity increases steadily with age in both species, but about a factor of 4 faster in the infant monkeys. The dotted line represents a mnemonic: Acuity in cycles per degree is roughly equal to age, in months for human infants and in weeks for monkey infants. (Reprinted from Teller, 1981, with permission of Elsevier Science.)

Two interesting trends are illustrated by these data. First, grating acuity is initially very poor—more than an order of magnitude poorer than adult acuity—and emerges gradually over a very long, slow time course, reaching adult levels only at three to five years for human infants and at about a year for monkey infants. Second, the growth curves for human and monkey infants are similar when plotted in months and weeks, respectively. The growth of grating acuity thus conforms well to the 4:1 rule often seen in measures of sensory and cognitive development: Human and macaque infants are similar at birth and have similar growth curves, but a week in the life of an infant monkey is like a month in the life of a human infant. To the precision at which they have been tested, other visual functions also conform reasonably well to this rule (e.g., Kiorpes, 1992). Accordingly, data from both species will be used interchangeably to illustrate the general developmental trends described below.

The development of spatial and temporal resolution

In this section, the development of grating acuity is compared with the development of three additional measures of spatial and temporal resolution: critical flicker frequency, stereoacuity, and vernier acuity.

CRITICAL FLICKER FREQUENCY The term critical flicker frequency (CFF) refers to the fastest temporal al-

ternation, or flicker, that an infant of a given age can discriminate from a steady (nonflickering) light. Regal (1981) showed that, surprisingly, even very young infants stare at rapidly flickering stimuli. A 1-month-old's CFF is about 40 Hz (cycles per second), while 2-month-olds, 3-month-olds, and adults have CFFs of about 50, 52, and 55 Hz, respectively. These data are important because they are so different from the long, slow time course of development of grating acuity. To our knowledge, CFFs have not yet been studied in infant monkeys.

STEREOACUITY Stereovision—the capacity to perceive depth on the basis of binocular disparity—was also an early target of developmental studies. The results of three early studies, using three very different experimental paradigms are summarized in figure 6.2. All three studies agree that responses to binocular disparity are absent in almost all infants under the age of 3 months, having their onset between 3 and 6 months postnatal. A similar time course of onset, in weeks rather than months, has also been demonstrated recently in infant monkeys (O'Dell and Boothe, 1997).

In the case of stereoacuity, the data from individual infants are also of interest. Figure 6.3 shows longitudinal data on the development both of grating acuity and stereoacuity in individual human infants (Held, Birch, and Gwiazda, 1980; Held, 1993). The onset of responsiveness to binocular disparity occurs at slightly different postnatal ages in different individual infants; but once the response appears, stereoacuity develops rapidly, reaching 1' disparity within a few weeks of the first response to large disparities. Such a rapid increase in vi-

FIGURE 6.2 Summary of early data on the development of responsiveness to binocular disparity. The circles show forced-choice preferential looking data from Birch, Gwiazda, and Held (1982) for crossed disparities of 58' (open circles) and 1' (closed circles). The large open squares show visual evoked potential data from Petrig et al. (1981). The triangles show behavioral data, including the data of Fox et al. (1979), plus additional unpublished data originally supplied by R. Aslin. (Reprinted with permission from Teller, 1982.)

sual function is unique to the case of binocularity. It is particularly striking, as shown in the figure, that large changes in stereoacuity occur over a time span that produces only minimal changes in grating acuity within the same infant.

VERNIER ACUITY Vernier acuity is a measure of sensitivity to small spatial offsets. For example, two vertical lines or gratings can be presented, one just above the other, with the top pattern offset slightly from exact alignment with the bottom. The subject's vernier acuity is the smallest visible offset between the two stimuli. Figure 6.4 summarizes data for both grating and vernier acuity in infant monkeys (Kiorpes, 1992). These data show a typical developmental time course for grating acuity and a larger developmental change with a consistently more rapid time course for vernier acuity. Both functions probably approach adult levels at about the same age, approximately 40–60 weeks. Longitudinal data from within each animal show a developmental course similar to that of the group average rather than the more abrupt developmental course seen in the case of stereopsis.

Comparisons to earlier human infant data (Manny and Klein, 1985; Shimojo et al, 1984) are also shown in figure 6.4, with ages converted by the 4:1 rule. While grating acuities agree well across species, vernier acuity is apparently higher at each age in infant monkeys than in human infants. However, both earlier studies used

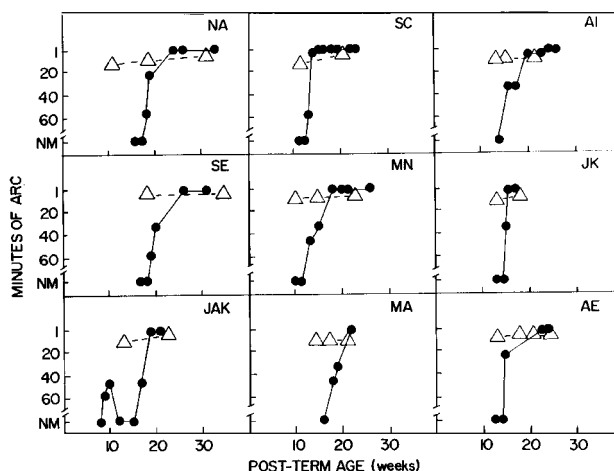

FIGURE 6.3 Longitudinal development of stereoacuity (closed circles) and grating acuity (open triangles) in the same individual infants. The ordinate shows stereoacuity in minutes of arc, and also grating acuity in minutes per 1/2 cycle (stripe) of the grating. The rapid growth in stereoacuity occurs at different ages in different infants, occurring as early as the 13th week in some infants (subject SC), and as late as the 19th week in others (subject SE). Within each infant, the growth of stereoacuity from 58' to 1' occurs remarkably rapidly, and more rapidly than suggested by the group averages in figure 6.2. During the same period, grating acuity changes little if at all in each case. (Reprinted with permission from Held, 1993.)

moving vernier offsets, while Kiorpes used stationary offsets; in all probability, a closer identity of stimulus parameters would yield a closer identity of developmental time courses (cf. Skoczensky and Aslin, 1992).

COMPARISONS OF RESOLUTION MEASURES ACROSS VISUAL FUNCTIONS Figure 6.5 shows a comparison of developmental time courses for grating acuity, vernier acuity, stereoacuity, and critical flicker frequency for human infants. In each case, the measured or estimated *adult* value is shown at the top of the graph, at zero on the ordinate. The acuity values at each age are then plotted as decrements with respect to the adult value on a logarithmically spaced ordinate. In such a plot, all values are plotted in log relative terms, so that physical units are eliminated. Such a plot (J. Palmer, personal communication) allows a basis for comparing the relative maturational time courses of different visual functions.

For CFF, the initial decrement is less than an octave—a factor of 2—and CFF rapidly approaches adult levels in early infancy. For grating acuity, in sharp contrast, the initial decrement is about seven octaves; and the developmental curve assumes the long, slow time course described earlier, reaching adult levels only at three to five years after birth. Stereoacuity shows a third pattern—it is

FIGURE 6.4 Longitudinal development of vernier acuity (right ordinate; lower points and dashed line) and grating acuity (left ordinate; upper points and solid line) in the same infant monkeys, plotted as a function of age in weeks. The two functions develop during a similar period, but vernier acuity starts out with a larger deficit and develops more rapidly. The larger symbols show data from earlier studies on human infants, plotted in months. The higher vernier acuity values seen in human infants in some studies are probably an artifact of stimulus differences among the studies. (Reprinted from Kiorpes, 1992, with permission of Cambridge University Press.)

unmeasurable until about three months postnatal. When first measurable, it is about eight octaves below estimated adult levels; but it rises rapidly to within two octaves of adult levels by six months in the group data, and even faster for each individual infant. Finally, vernier acuity shows an initial decrement of perhaps seven octaves, improving at first rapidly and then more slowly with age, with a time course reminiscent of that for grating acuity, but delayed in time (cf. Carkeet, Levi, and Manny, 1997).

Contrast sensitivity functions

Next we examine more extensive data on the development of spatial and temporal vision—spatial and temporal contrast sensitivity functions. The spatial contrast sensitivity function (CSF) describes a subject's sensitivity to sinusoidal gratings of various spatial frequencies. Similarly, the temporal contrast sensitivity function (tCSF) describes a subject's sensitivity to sinusoidal modulations of various temporal frequencies. Logically, there are several ways in which a CSF or a tCSF could change during development: it could shift vertically in sensitivity, or horizontally in spatial or temporal scale; or it could remain constant in sensitivity and scale, but mani-

FIGURE 6.5 Summary of maturational rates for four different kinds of visual resolution: critical flicker frequency (from Regal, 1981), grating acuity, stereoacuity, and vernier acuity (from Gwiazda, Bower, and Held, 1989). The dotted line shows the measured or estimated adult acuity value. The log acuity decrement shown by infants in relation to the adult value is plotted as a function of age (from J. Palmer and D. Peterzell, personal communication). (Reprinted from Teller, 1997, with permission of the Association for Research in Vision and Ophthalmology.)

FIGURE 6.6 Spatial contrast sensitivity functions measured longitudinally in a single infant monkey, at six ages between 10 weeks (lowest curve) and 38 weeks (highest curve). The contrast sensitivity function exhibits shifts upward, in sensitivity, and rightward, in spatial scale. (Reprinted from Boothe et al., 1988, with permission of Elsevier Science.)

fest changes in fundamental curve shape. These different kinds of change have different implications within well-established theories of adult visual function (see Teller, 1998, for further discussion). In fact, CSFs and tCSFs show different patterns of change.

SPATIAL CONTRAST SENSITIVITY FUNCTIONS (CSFs)
A set of CSFs collected longitudinally from a single infant monkey is shown in figure 6.6 (Boothe et al., 1988). Interestingly, the CSF shifts both vertically and horizon-

Luminance Gratings

○ MOVING
□ COUNTERPHASE

FIGURE 6.7 Temporal contrast sensitivity functions for 3-month-old infants and adults, for both luminance-modulated (left) and red/green chromatic gratings (right). For luminance-modulated gratings, infants show a simple shift in sensitivity.

tally during development. It has been argued that when test conditions are held constant, CSFs at all ages can be fitted with the same shape-invariant curve, shifted only vertically in sensitivity and horizontally in spatial scale (Movshon and Kiorpes, 1988). The same rule seems to hold for CSFs for red/green chromatic stimuli (e.g., Kelly, Borchert, and Teller, 1997).

TEMPORAL CONTRAST SENSITIVITY FUNCTIONS (tCSFs) tCSFs from 3-month-old infants and adults (Dobkins, Lia, and Teller, 1997) are shown in the left panel of figure 6.7. With respect to those of adults, infant tCSFs show a large loss of sensitivity. In both infants and adults, tCSFs peak near 6 Hz and are nearly identical in shape. Thus, while infant spatial CSFs manifest shifts in spatial scale as discussed above, no analogous shift in temporal scale seems to occur.

In addition to sensitivity to variations in intensity, or luminance, human infants show sensitivity to variations in chromaticity, or color (reviewed in Teller and Bornstein, 1987; Brown, 1990; Teller, 1998). Dobkins, Lia, and Teller (1997) tested tCSFs for red/green isoluminant gratings—that is, red/green gratings in which the red and green bars were matched in luminance, and varied only in chromaticity. The red/green gratings flickered in

Chromatic Gratings

● MOVING
■ COUNTERPHASE

For chromatic gratings, there is a major change in curve shape, with adults showing a low-pass function and infants showing a band-pass function. (Reprinted from Dobkins, Lia, and Teller, 1997, with permission of Elsevier Science.)

counterphase; that is, the red and green bars reversed in location, at a rate of 12 reversals per second (6 Hz). In adults, tCSFs for isoluminant red/green gratings are low-pass, as shown in the right panel of figure 6.7. However, tCSFs for red/green gratings are band-pass in 3-month-olds. Thus, infants' responses to flickering red/green gratings provide the first example of a change in curve shape between infancy and adulthood.

In summary, the development of vision is complex rather than simple. Different visual functions emerge over different postnatal epochs, with different time courses and different kinds of changes of functional relationships.

Mechanisms of visual development

These behavioral data on vision and visual development immediately raise questions about neural mechanisms. What and where are the immaturities in the young infant's visual system that allow temporal resolution to be almost adult-like, grating acuity to be reduced by an order of magnitude, and the response to binocular disparity not to happen at all?

As discussed by Rakic (chapter 1 of this volume) and Bourgeois, Goldman-Rakic, and Rakic (chapter 4 of this

volume), many postnatal anatomical changes are well documented in the visual system of infant primates; consider, for example, the period of intense synaptogenesis and the segregation of ocular dominance columns during the first two to three postnatal months in infant monkeys, the long slow development of the fovea (Yuodelis and Hendrickson, 1986), and the late maturation of local cortical circuits (Burkhalter, Bernardo, and Charles, 1993) documented in human infant tissue. Physiological development is much less well documented, with only a dozen or so studies in print at present.

Moreover, causal relationships between behavior and substrate are notoriously difficult to establish. Visual functions mature because the neural substrate matures, and the causes of functional maturation undoubtedly lie in neural maturation. But the length of the big toe matures too, yet we do not see it as causal in relation to the development of grating acuity. The puzzle is, which of the many immaturities of the neural substrate provide the *critical immaturities* (Brown, 1990) that limit a particular visual capacity at a particular age? Temporal coincidences become convincing causal stories only as a result of quantitative theoretical argument. The following paragraphs provide brief vignettes of some of the models and speculations that currently attempt to provide bridges between anatomy, physiology, and behavior.

OPTICS AND ACCOMMODATION The optical quality of the primate eye is excellent at birth, and places no major limitations on visual acuity or other visual functions (see Banks and Bennett, 1988, for a review). Moreover, the development of accommodation (the capacity of the lens of the eye to change its focal length in order to focus on objects at varying distances) provides an example of an immaturity that is probably not a critical immaturity. Newborn infants typically do not accommodate differentially for objects at different distances (Haynes, White, and Held, 1965), and it might be thought that the resulting blur in the retinal image would contribute to their reduced grating acuity. However, the opposite direction of causality is more likely. That is, if the infant's visual system cannot process high spatial frequencies (see below), the infant has no need to accommodate, and no basis for generating signals that would lead to changes in accommodation.

FOVEAL IMMATURITIES AND SPATIAL VISION The profound and long-lasting anatomical immaturities of the primate fovea (Yuodelis and Hendrickson, 1986) provide a more likely critical immaturity for limiting infant acuity and contrast sensitivity. At birth, infants' foveal cones are coarsely packed, having very short outer segments and probably inferior waveguide properties.

These characteristics drastically reduce the foveal quantal catch in infants compared to adults, and should therefore (due to quantal fluctuations) reduce the overall sensitivity of infants' vision by tenfold or more (Banks and Bennett, 1988). In addition, the change in cone packing density (in combination with changes in eye size) affords a predicted change in spatial scale of about 1:4 between birth and adulthood, in remarkably good correspondence with the spatial scale shift seen in infant CSFs (see figure 6.6; Kelly, Borchert, and Teller, 1997). Several exemplary quantitative models of the effects of foveal immaturity on infant acuity and contrast sensitivity have been developed (Banks and Bennett, 1988; Banks and Crowell, 1993; Brown, Dobson, and Maier, 1987; Jacobs and Blakemore, 1988; Movshon and Kiorpes, 1993; Wilson, 1988, 1993).

Single unit recordings from monkey lateral geniculate nucleus (LGN) show that the LGN neurons with the best spatial resolution have acuities of only about a factor of 2 higher than the behaviorally measured acuities of infant monkeys (Blakemore and Vital-Durand, 1986; Hawken, Blakemore, and Morley, 1997). Thus most, but not all, of the limit on infant grating acuity and the reductions in sensitivity and spatial scale seen in infants' CSFs are probably caused at the earliest stages of visual processing.

Moreover, these losses of sensitivity and spatial scale will doubtless play through importantly to influence the development of many other visual functions. For example, Banks and Bennett (1988) have argued quantitatively that the known foveal immaturities are sufficient to predict the development of vernier acuity in infants. This conclusion is initially surprising, because the visual processing required to analyze vernier offsets in adults is often attributed to visual cortex. However, a function limited by a particular critical locus in the adult can nonetheless be limited by a critical immaturity *at a different locus* in the infant. An adequate model for the development of each visual function will have to incorporate the effects of foveal immaturities before an argument for more central critical immaturities can be maintained.

TEMPORAL PROCESSING The anatomical and physiological elements that control infants' temporal processing capabilities (CFFs and tCSFs) remain obscure, and data are scarce. The only available temporal response functions of single neurons in early infancy, obtained in neonatal vervet monkey LGN, peak at low temporal frequencies (Hawken, Blakemore, and Morley, 1997), and these authors conclude that the temporal resolution of single LGN cells increases considerably postnatally. These data would lead one to expect changes in temporal scale—rightward shifts of the tCSF—with develop-

ment, but no such shift is seen in the behavioral data (figure 6.7). The discrepancy between the physiologically based prediction and the behavioral facts remains to be reconciled.

M VS. P PATHWAYS IN EARLY VISUAL PROCESSING
Modern anatomical and physiological studies suggest the presence of (at least) two distinct pathways from the retina to cortical area V1 (for a review see Merigan and Maunsell, 1993). These are the M or *magnocellular* pathway, and the P or *parvocellular* pathway. Global models of visual development have occasionally been proposed in which the P pathway precedes the M pathway in development or vice versa. It seems more likely that each pathway has its own course of development, with different functional capabilities of each pathway developing at different rates.

In adults, M-initiated signals are thought to dominate the tCSF for luminance-modulated stimuli, while P-initiated signals are thought to dominate the tCSF for chromatic stimuli. On the basis of their observation of band-pass tCSFs for red/green chromatic modulation in infants, Dobkins, Lia, and Teller (1997) speculated that in the immature visual system, temporally modulated red/green gratings might be detected via M- rather than P-initiated signals. Such an outcome suggests either that temporal resolution in the M pathway matures earlier than temporal resolution in the P pathway, or that the tCSF of P cells changes from band-pass to low-pass during development. In any case, the change in shape of the chromatic tCSF between infancy and adulthood is unique in the infant vision literature, and clearly invites study and modeling at the physiological level.

STEREOPSIS The development of stereopsis provides a final example. Anatomically, ocular dominance columns in primates are not fully segregated at birth, and continue to segregate over the early postnatal weeks or months (Hubel, Wiesel, and LeVay, 1977; Horton and Hocking, 1996). Thus, there is a general temporal coincidence between the end of anatomical segregation of ocular dominance columns and the onset of responses to large binocular disparities.

On this basis, Held (1985) proposed a model of the development of stereovision. In the adult, neurons in layer 4 of cortical area V1 are monocular, with some neurons driven by the left eye and others by the right. Held hypothesized that in very young infants, left-eye and right-eye inputs might converge too early, on the neurons in layer 4, making them binocular rather than monocular. This convergence was hypothesized to cause a loss of eye-of-origin information, and a conse-

quent disabling of disparity selectivity of neurons in the upper cortical layers. In this view, the onset of stereopsis could be caused by the sorting out of left-eye and right-eye inputs in layer 4, enabling disparity detectors to work.

Surprisingly, it took 12 years before physiological data bearing on this hypothesis became available. Using a binocular phase paradigm, Chino et al. (1997) showed recently that in infant monkeys, in contradiction to the hypothesis, both the ocular dominance properties and the disparity selectivity of neurons in V1 are adult-like at birth. The Chino study also confirmed earlier findings (Blakemore and Vital-Durand, 1981) that the sensitivity and spatial tuning properties of V1 neurons are immature (as they are at the LGN and presumably at the retina). Chino and colleagues argue that changes in sensitivity and spatial scale alone are sufficient in principle to produce changes in the infant's behavioral response to binocular disparity. For example, sensitivity to a fixed interocular phase difference, in combination with a shift of the CSFs of neurons toward higher spatial frequencies, will yield sensitivity to smaller absolute disparities.

A quantitative theoretical account of how the early changes in sensitivity and spatial scale should play through to influence stereoacuity remains to be developed. Such a theory might suggest that foveal immaturities should yield quantitatively different developmental time courses for grating acuity and disparity sensitivity (as Banks and Bennett, 1988, argue for grating acuity and vernier acuity). But even so, it is difficult to see how the same changes in sensitivity and scale could allow both the negligible changes of grating acuity and the very rapid improvement of stereoacuity seen in postnatal months 3–6 (figures 14.2, 14.3, and 14.5).

It seems likely that a second critical immaturity will be needed to account for the rapid development of stereopsis. This mechanism did not reveal itself in Chino's binocular-phase-based study of V1 neurons. The rapid development of stereoacuity (like the change in the shape of the chromatic tCSF) cries out for further theoretical and experimental analysis, particularly with stimuli that more closely resemble the stimuli used in the behavioral studies.

In sum, in a curious modern repetition of the history of visual science at the adult level, we know much more about the development of visual functions than we do about the development of visual physiology. It seems certain that the tentative causal stories presented here will be rewritten as more extensive physiological data become available, and as more and more sophisticated experimental paradigms are used (e.g., Chino et al., 1996; Movshon et al., 1997; Hatta et al., 1998).

Summary and conclusions

Infant vision research provides an interesting model for the neurobiology of development. It highlights a set of well-understood techniques for measuring the visual capacities of infants, basic descriptions of the development of many visual functions, and a behaviorally established animal model for asking causal questions. Quantitative anatomical and physiological data are becoming available; and quantitative visual theory is being imported into the discipline and used to evaluate hypotheses about the dependence of visual behavior on visual physiology and visual substrate in the developmental context.

And yet, there is work to be done at the metatheoretical level. Coincidences of time scale and similarities of curve shape between psychophysical, anatomical, and physiological data are the beginning, not the end, of theoretical explanations; and the concept of critical immaturity (Brown, 1990), like that of critical locus (Teller, 1980), will require continuing scrutiny, both at the abstract level and when imbedded implicitly or explicitly in causal stories intended to relate visual function to visual substrate. Similar analyses might be useful in other domains of cognitive neuroscience.

One final question can be raised: Why do vision and the visual system bootstrap themselves in the particular sequence that they do? Why is a visual world with poor visual acuity and contrast sensitivity, poor sensitivity to color differences, and no stereopsis sufficient for young infants, while excellent representation of the temporal properties of stimuli is apparently required? Which of these developmental time courses are direct products of natural selection acting on infant behavior, and which are accidental consequences of other evolutionary pressures? It is easy to speculate that natural selection favors infants who perceive depth and distance before they can crawl; but beyond this, we know little about the reasons for the pattern of emergence of different visual functions over the course of infancy.

Specificity and Plasticity in Neurocognitive Development in Humans

HELEN J. NEVILLE AND DAPHNE BAVELIER

ABSTRACT Brain imaging studies of adults who have had altered sensory and language experience and studies of normally developing children during sensory and language processing tasks are summarized. The results suggest that different subsystems within vision and within language display different degrees of experience-dependent modification of cortical organization. Within vision, the organization of systems important in processing peripheral space and motion information is most altered following auditory deprivation. Within language, delayed exposure to a language has pronounced effects on the development of systems important in grammatical processing, and has many fewer effects on lexical development. Hypotheses concerning the origins of these differential effects of early experience are discussed.

Cognitive neuroscience has rapidly expanded during the decade of the brain. Progress in cognitive science and in the development of techniques that permit noninvasive monitoring of the human brain have permitted extensive, ongoing mapping and differentiation of sensory and cognitive systems in the mature human mind/brain. The burgeoning literature on the normal adult brain serves as the point of departure for a major opportunity and challenge for the coming decade and century—the characterization of the processes that lead to the development and differentiation of the mature brain (developmental cognitive neuroscience).

Discussions of neurocognitive development have long been dominated (and stifled) by the “nature–nurture” debate. Most current investigators acknowledge both the role of biological constraints imposed by the genotype and the role of environmental inputs in gene expression and other chemical and physiological developmental events. It is clear that neurocognitive development relies on a dynamic and complex interplay between predetermined genetic events and environmental events. In this chapter we argue that the degree of interplay is highly

variable across different neurocognitive systems, leading to different degrees and timing of sensitivities to environmental inputs for different brain functions. These differences in developmental specificity and plasticity prevent simple generalization and call for a careful characterization of the developmental events within each system and subsystem.

This chapter offers (1) evidence on the development of the anatomy of the developing cerebral cortex in humans; (2) a review of developmental plasticity of higher visual functions, considering separately functions of the ventral and dorsal visual pathways; (3) a brief discussion of reports on plasticity within the development of other sensory systems; and (4) a consideration of developmental plasticity and specificity of language functions with an emphasis on the comparison of lexical and grammatical functions.

Anatomy and physiology of the developing human brain

Although a thorough review of the structural, chemical, and physiological development of the human brain is beyond the scope of this chapter, this section aims at summarizing the state of knowledge on postnatal human development from infancy to adulthood.

In most species, including humans, the developing brain displays progressive and regressive events during which axons, dendrites, synapses, and neurons show exuberant growth and major loss leading to a remodeling of the neural circuitry. This period of remodeling is hypothesized to be a time during which environmental factors can have a major impact on cortical organization. Several studies of primary sensory areas have shown that sensory inputs are of central importance in selecting the axons, dendrites, synapses, and neurons that form functional neural circuits (Rakic, 1976; Hubel and Wiesel, 1977; Sur, Pallas, and Roe,

1990). For example, during a specific time period (the sensitive period), visual deprivation induced by monocular eyelid suture results in shrinkage of ocular dominance columns serving the closed eye. Outside the critical period, visual deprivation has little effect on the pattern of ocular dominance (Blakemore, Garey, and Vital-Durand, 1978; Hubel and Wiesel, 1977; Horton and Hocking, 1997). Little is known about the factors that control the duration and timing of sensitive periods; however, the onset of the sensitive period is affected by input. For example, in cats, binocular deprivation results in delayed onset of the sensitive period for ocular dominance formation (Cynader and Mitchell, 1980; Mitchell, 1981). Similar observations have been made in the auditory system of songbirds (Marler, 1970) and humans. The maturation of an early auditory evoked response displays an extended time course of development after cochlear implantation in congenitally deaf children (Ponton et al., 1996). The number of years of auditory experience, rather than chronological age per se, was predictive of the maturational time course.

Different neural systems and associated behavioral capabilities are affected by environmental input at highly variable time periods, supporting the idea that they develop along distinct time courses (Mitchell, 1981; Harwerth et al., 1986; Curtiss, 1989; Neville, Mills, and Lawson, 1992; Maurer and Lewis, 1998). For example, visual processes thought to arise within the retina (cf. the sensitivity of the scotopic visual system) display relatively short sensitive periods. By contrast, binocular functions that rely on later developing cortical neurons display considerably longer sensitive periods (Harwerth et al., 1986). This variability in the timing of experience-dependent modification may depend upon the rate of maturation of the neural systems that mediate different functions, with later developing cortical areas having more opportunity to be affected by incoming input.

The proposal that different brain systems in the human display distinct developmental time courses is supported by anatomical and physiological measurements. Recently developed neuroanatomical techniques can be used to provide estimates of the density of neurons, axons, dendrites, or synapses in tissue. Huttenlocher and collaborators (Huttenlocher, 1994; Huttenlocher and Dabholkar, 1997) have used electron microscopy to map out the synaptic remodeling that occurs during human development. These authors have compared synaptogenesis and synapse elimination within several different brain areas (Huttenlocher, 1994). In primary visual cortex a burst in synaptogenesis occurs at about 3 to 4 months of age, with the maximum density reached at 4

months. In contrast, synaptogenesis in the middle prefrontal cortex takes longer, reaching a maximum synaptic density at about 3.5 years of age. Furthermore, the time course for synapse elimination occurs significantly later in the middle frontal gyrus (until age 20) than in the primary visual cortex (converged on adult levels by age 4; see figure 7.1; Huttenlocher and Dabholkar, 1997). Recently, Huttenlocher and colleagues have described developmental changes in synaptic density for different cortical areas important in language processing—primary auditory cortex, the angular gyrus (Brodmann's area 40), and Broca's area (Huttenlocher, 1994; Huttenlocher and Dabholkar, 1997). At birth synaptic development (as measured by the time course of synaptic density) in the auditory cortex is more advanced than in the two language areas; but by 4 years of age, synaptic density is similar in these areas and is significantly greater than in the adult (by about a factor of 2). These findings suggest different time courses of synaptogenesis for different brain systems. A recent report suggests there may also be considerable postnatal variability in neuron loss and neurogenesis in the human brain (Shankle et al., 1998b). However, other neuroanatomic features of the human brain appear to show concurrent developmental patterns from region to region (Shankle et al., 1998a). In macaque monkeys, Rakic and colleagues (1986) have reported concurrent time courses of synaptogenesis across several different brain areas. However, there is variability between areas in the duration of the maximum densities of synapses, in the elimination phases, and in the timing of synaptogenesis on dendritic shafts and spines (see chapter 4 of this volume).

Anatomical measures of synapse proliferation in the human brain (Huttenlocher and Dabholkar, 1997) describe developmental time courses similar to those observed in physiological studies using PET with FDG, a technique that traces glucose metabolism. Chugani and collaborators (1996) have described the patterns of brain glucose utilization during human development. These studies show a rapid rise in cerebral metabolism during infancy, perhaps reflecting the burst of synaptogenesis described in the structural studies. This is followed by a decrease in brain glucose metabolism later in childhood, in much the same time frame as is observed for the loss of synapses. In the metabolic studies, primary sensory and motor cortex, the hippocampal region, and the cingulate cortex have an earlier increase in glucose metabolism than other cortical regions; and the prefrontal cortex is one of the latest structures to show increased glucose metabolism. These structural and physiological findings support the view of different maturational time-tables for distinct brain structures with primary cortices developing before higher association cortices.

FIGURE 7.1 Mean synaptic density in synapses/100 μm^3 in auditory (filled circles), calcarine (open circles), and prefrontal (x's) cortex at various ages. (Reprinted from Huttenlocher and

Dabholkar, 1997, by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

Much more research is necessary to characterize the structural and physiological development of the human brain and to link variability in the development of these parameters to variability in the time course of sensory, motor, and cognitive development in the child.

Developmental specificity of visual functions in humans

We now have powerful brain imaging methods to study aspects of the physiology of sensory and language processing in humans. Event-related brain potentials (ERPs) and functional magnetic resonance imaging (fMRI) are two such techniques. ERPs are voltage fluctuations in the EEG in response to a controlled stimulus. The latencies of different positive and negative components in an ERP reveal the time course of activation (within microseconds) of the neuronal populations that are recruited during the processing of that stimulus. The fMRI technique measures changes in blood flow and oxygenation, permitting mapping of brain regions metabolically active following the presentation of a controlled stimulus. In contrast to the ERP, this technique has a good spatial resolution (about 1 mm) but a restricted temporal resolution.

DORSAL AND VENTRAL VISUAL SUBSYSTEMS In several experiments employing ERPs, we have observed that sensory and attentional processing of visual information presented to the central and peripheral visual fields elicit activity in different neural pathways in normal hearing subjects. Congenital auditory deprivation is associated with specific enhancements of behavioral performance and ERPs in response to visual information presented in the peripheral (but not the foveal) visual fields (Neville, Schmidt, and Kutas, 1983; Neville and Lawson, 1987a, b, c). These data suggest that the systems mediating the representation of peripheral visual space may be more modifiable than those representing central visual space. There is anatomical evidence that the visual periphery is represented most strongly along the dorsal visual pathway that projects from V1 toward the posterior parietal cortex and includes areas important for the processing of spatial location and motion information. By contrast, central space is largely represented along the ventral pathway that projects from V1 to anterior regions of the inferior temporal lobe and includes areas important for processing form and color information (Ungerleider and Mishkin, 1982; Baizer, Ungerleider, and Desimone, 1991). These results prompted the

hypothesis that there may be a greater sensitivity to altered experience for other dorsal visual pathway functions.

In order to investigate this hypothesis, we employed stimuli designed to selectively activate either the magnocellular system (M stimuli) which projects strongly to the dorsal pathway, or the parvocellular system which projects strongly (but not solely: see Stoner and Albright, 1993; Sawatari and Callaway, 1996) to the ventral pathway (P stimuli). The parvo system is highly responsive to color information and to stimuli of high spatial frequency, while the magno system is highly responsive to motion and to stimuli of low spatial frequency and low contrast (Livingstone and Hubel, 1988; Merigan and Maunsell, 1993).

Stimuli were presented at five different locations including the fovea and 8 degrees from the foveal stimulus in the upper and lower left and right visual fields. The parvo (P) stimuli were isoluminant blue and green high spatial frequency gratings (adjusted for the cortical magnification factor) continuously visible at all locations. ERPs were evoked by a brief change in color; randomly at one location the blue bars changed to red for 100 ms. The magno (M) stimuli consisted of low spatial frequency gratings of light and dark gray bars with a low luminance contrast. The evoking stimulus consisted of the bars at one location (random) moving transversely to the right. Subjects fixated centrally and monitored all locations for the rare occurrence of a black square at one of the locations. We first asked whether ERPs to these different stimuli would provide evidence for the activation of distinct neural systems in normal hearing subjects and then asked whether congenital auditory deprivation would have selective effects on these different aspects of processing (Armstrong et al., 1995; Neville and Bavelier, 1998).

In normal hearing subjects the distribution of the ERPs elicited by the parvo and magno stimuli displayed many similarities, and this may be attributable to the spatial proximity (within 1 cm) of the ventral and dorsal stream areas in humans, as indicated in recent fMRI studies (Sereno et al., 1995; Tootell et al., 1995). On the other hand, there were reliable differences in the activity patterns elicited by the stimuli. Magno stimuli elicited responses that were larger dorsally than were responses to parvo stimuli, consistent with our initial hypotheses. Additionally, both the current source density maps and the grand averaged waveforms demonstrate that, whereas the peripheral M stimuli elicited ERPs largest over cortex contralateral to the field of presentation, the P stimuli evoked a bilateral response. This pattern of results may be attributable in part to the deep ventromedial location of V4 which could generate a bilateral

pattern of activation. Area MT, on the other hand, is located more laterally and would therefore generate a stronger contralateral response. Thus, these differences are consistent with anatomical differences of ventral and dorsal stream areas.

In addition, magno stimuli elicited ERP responses with considerably earlier latencies than those elicited by parvo stimuli, consistent with evidence from animal studies that show faster conduction within the magnocellular pathway. In addition, for several early components (beginning at 110 ms), P stimuli presented in the upper and lower visual fields (VF) evoked different response amplitudes while magno stimuli did not. These results may be accounted for by the retinotopic organization of V4 and MT/MST. fMRI data from humans (Sereno et al., 1995) have shown that upper and lower VF representations in several ventral stream areas including V4 are centimeters apart; however, in areas MT and MST, the representations are adjacent. Thus, a difference in response to parvo stimuli in the upper and lower VF is consistent with ventral stream activation, and the similarity of responses to magno stimuli in the upper and lower VF is consistent with dorsal stream activation. In summary, these stimuli were successful in evoking distinct ERP responses that may index the activation of separate streams or modes of visual processing in normal hearing subjects.

EFFECTS OF AUDITORY DEPRIVATION Our prior research, coupled with evidence that different systems within vision display different developmental time courses and modification by visual experience (Sherman, 1985), led us to hypothesize that processing of the magno stimuli would be selectively enhanced in congenitally deaf subjects.

Subjects were 11 congenitally, profoundly and bilaterally deaf subjects born to deaf parents. Whereas hearing subjects' reaction times were faster to targets occurring in the central than in the peripheral visual field, deaf subjects responded equally quickly to targets in the central and peripheral fields. Several specific group differences occurred in the amplitude and distribution of early sensory responses recorded over anterior and temporal regions. Deaf subjects displayed significantly greater amplitudes than hearing subjects—but this effect occurred only for magno stimuli, not for parvo stimuli (see figure 7.2). Further, whereas in hearing subjects, P stimuli elicited larger responses than did M stimuli, in deaf subjects responses to M stimuli were as large as those to P stimuli. In addition, at 150 ms ERPs to the M stimuli displayed a source-sink generator in temporal cortex that was clearly present in the deaf subjects but not in the hearing subjects. Currently, we are acquiring

FIGURE 7.2 ERPs elicited by (a) color change and (b) motion in normally hearing and congenitally deaf adults. Recordings from temporal and posterior temporal regions of the left and

right hemispheres. (Reprinted with permission from Neville and Bavelier, 1998.)

results from a group of hearing subjects born to deaf parents who acquired ASL as a first language. This research should allow us to determine whether certain group effects observed in this experiment are attributable to auditory deprivation and others to acquisition of a visuospatial language (ASL) since, in previous research, we have observed separate effects of these two factors (Neville and Lawson, 1987c).

These data suggest that there is considerable specificity in the aspects of visual processing that are altered following auditory deprivation; specifically, the dorsal visual processing stream may be more modifiable in response to alterations in afferent input than is the ventral processing pathway. This hypothesis is in broad agreement with the proposal put forward by Chalupa and Dreher (1991) that components of the visual pathway

that are specialized for high acuity vision exhibit fewer developmental redundancies ("errors"), decreased modifiability, and more specificity than do those displaying less acuity and precision. It may also be that the dorsal visual pathway has a more prolonged maturational time course than the ventral pathway, permitting extrinsic influences to exert an effect over a longer time. While little evidence bears directly on this hypothesis, anatomical data suggest that, in humans, neurons in the parvocellular layers of the LGN mature earlier than those in the magnocellular laminae (Hickey, 1977) and, in nonhuman primates, the peripheral retina is slower to mature (Lachica and Casagrande, 1988; Packer, Hendrickson, and Curcio, 1990; Van Driel, Provis, and Billson, 1990). Additionally, data suggest that the development of the Y-cell pathway (which is strongest in the periphery of

RESPONSES TO SPEECH

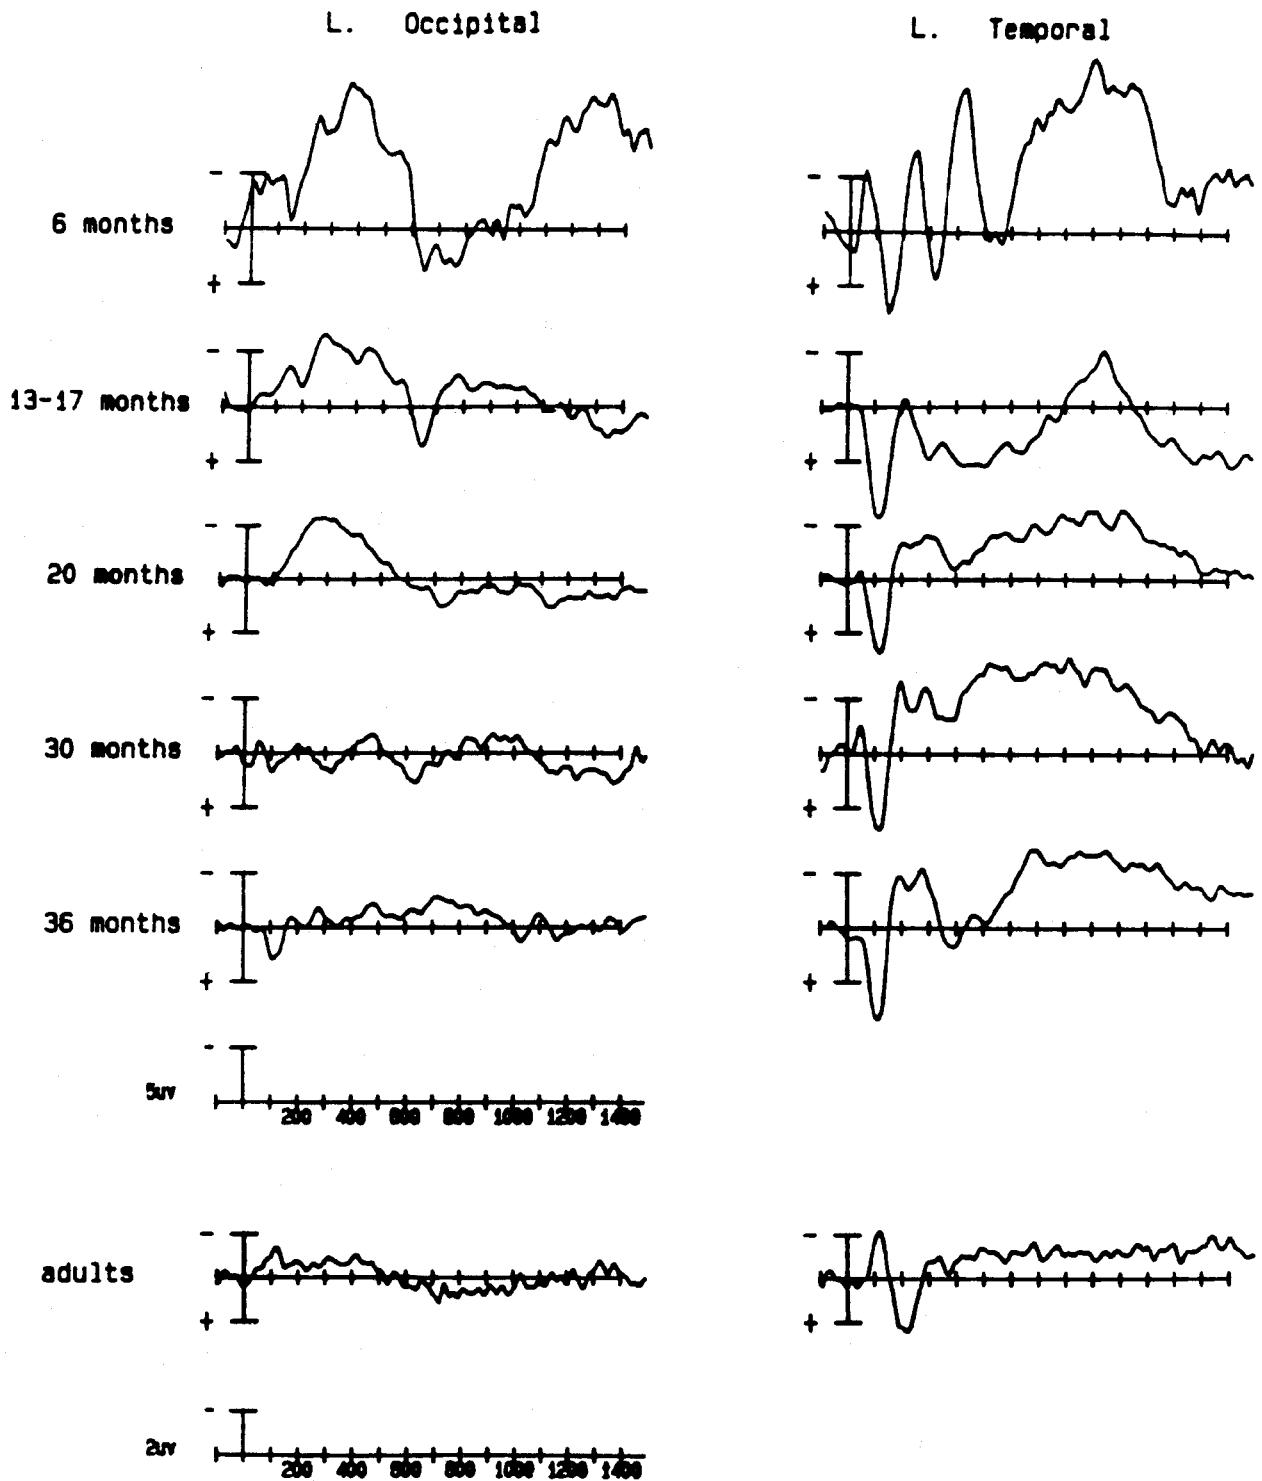

FIGURE 7.3 ERPs to auditory (speech) stimuli recorded over temporal and occipital regions in normal adults (bottom) and

in children aged 6–36 months. (Reprinted with permission from Neville, 1995.)

the retina) is more affected by visual deprivation than is development of the W- and X-cell pathways (Sherman and Spear, 1982). Investigators have also reported that the effects of congenital visual deprivation (due to cataracts) are more pronounced on peripheral than foveal vision (and by implication on the dorsal pathway) (Mioche and Perenin, 1986; Bowering et al., 1997). Moreover, in developmental disabilities including dyslexia, specific language impairment, and Williams syndrome, visual deficits are more pronounced for dorsal than ventral visual pathway functions (Lovegrove, Garzia, and Nicholson, 1990; Eden et al., 1996; Atkinson et al., 1997). An additional hypothesis that may account for the greater effects on peripheral vision is that in development the effects of deprivation and enhancement are equivalent within all cortical regions. Those areas with less extent to begin with (e.g., MT, peripheral visual representations) would display the largest proportional effects of both enhancement and vulnerability. A similar hypothesis has been proposed to account for the larger effects of visual deprivation on ocular dominance formation within the periphery in monkeys (Horton and Hocking, 1997).

SENSITIVE PERIOD EFFECTS AND MECHANISMS We have observed that individuals who became deaf after the age of 4 years (due to delayed expression of the gene that leads to cochlear degeneration) typically do not display the increased visual ERPs that we attributed to auditory deprivation (Neville, Schmidt, and Kutas, 1983; Neville and Lawson, 1987c). We considered several mechanisms that might mediate the effects themselves and the developmental time limits on them. One possibility is that they are mediated by an early, normally transient, redundancy of connections between the auditory and visual systems (as has been observed in cats and hamsters: see Dehay, Bullier, and Kennedy, 1984; Frost, 1984; Innocenti and Clarke, 1984). In the absence of competition from auditory input, visual afferents may be maintained on what would normally be auditory neurons. Our results from studies of later deafened individuals suggest that in humans this redundancy may diminish by the fourth year of life. One way we tested this hypothesis was to study the differentiation of visual and auditory sensory responses in normal development (see figure 7.3). In normal adults, auditory stimuli elicit ERP responses that are large over temporal brain regions but small or absent over occipital regions. By contrast, in 6-month-old children we observed that auditory ERPs are equally large over temporal and visual brain regions, consistent with the idea that there is less specificity and more redundancy of connections between auditory and visual cortex at this time. Between 6 and 36 months, however, we ob-

served a gradual decrease in the amplitude of the auditory ERP over visual areas, while the amplitude over the temporal areas was unchanged. These results suggest that early in human development there exists a redundancy of connections between auditory and visual areas and that this overlap gradually decreases between birth and 3 years of age. This loss of redundancy may be the boundary condition that determines when auditory deprivation can result in alterations in the organization of the visual system. Ongoing studies of hearing and deaf infants and children employing the parvo and magno stimuli described above will test for the specificity of these effects.

fMRI STUDY OF MOTION PERCEPTION We have further pursued the hypothesis that deafness alters the functional organization of the dorsal visual stream, by employing fMRI (Tomann et al., 1998). Specifically, we assessed whether early auditory deprivation alters cerebral activation during motion processing. In addition, we hypothesized that these changes would be most marked when visual attention was required in view of the central role of dorsal parietal regions in spatial attention. Motion processing was compared between congenitally deaf (native signers/born to deaf parents) and hearing individuals as visual attention was manipulated. Subjects fixated centrally and viewed an alternation of radial flow fields (converging and diverging) and static dots. While the first run required only passive viewing, visual attention was manipulated in all other runs by asking subjects to detect velocity and/or luminance changes.

Under conditions of active attention, deaf individuals showed a greater number of voxels activated and a larger percent signal change than did hearing subjects in temporal cortex including areas MT-MST (figure 7.4; see color plate 1). Thus, congenital deafness alters the cortical organization of motion processing, especially when attention is required. Interestingly, the recruitment of the intraparietal sulcus was also significantly larger in deaf than in hearing subjects. This result, like our earlier ERP study of spatial attention (Neville and Lawson, 1987b; Neville, 1995), suggests that early auditory deprivation may also alter the cortical organization of visual attention. Ongoing studies will determine the precise location and the specificity of these effects.

Developmental specificity in other neurocognitive domains

Developmental plasticity has also been documented in humans within other sensory modalities. There are several reports that early peripheral blindness leads to changes in the visually deprived cortex. Measures of glucose utilization have shown an increased metabolism

MOTION RELATED ACTIVATION MONITOR BRIGHTNESS CHANGES

HEARING

DEAF

FIGURE 7.4 Activation (fMRI, 1.5T) in normally hearing and congenitally deaf adults in response to visual motion.

in the visual cortex of early blind humans as compared to subjects who became blind after the completion of visual development. These studies report that metabolic activity within the occipital cortex of early blind individuals is higher than that found in blindfolded sighted subjects and equivalent to that of sighted subjects with their eyes open (Wanet-Defalque et al., 1988; Veraart et al., 1990; Uhl et al., 1994). Additionally, ERP studies indicate a larger slow negative DC potential shift over the occipital lobe in early blind than in sighted persons during tactile and auditory tasks (Uhl et al., 1991, 1994; Röder et al., 1996, 1997). Recently, a number of studies have confirmed the functional participation of visual areas during somatosensory tasks in early blind individuals. Using PET, Sadato and colleagues (Sadato et al., 1996) compared tactile discrimination in early blind braille readers and control subjects. Blind subjects revealed activation of visual cortical areas whereas these regions were deactivated

in controls. The functional relevance of visual areas in tactile discrimination was further established in a transcranial magnetic stimulation experiment (Cohen et al., 1997). Transient stimulation of the occipital cortex induced errors on a tactile task in early blind subjects but had no effect on the sighted controls. It is worth noting that not all aspects of somatosensory processing recruit visual areas in blind subjects. For example, simple tactile stimuli that did not require discrimination produced little activation in visual areas of blind subjects (Sadato et al., 1996). This finding is in agreement with the hypothesis that different neurocognitive systems and subsystems exhibit different sensitivities to altered experience.

This point is further supported by the research of Röder and colleagues (1997) who have studied auditory localization abilities in blind humans. ERPs were recorded as congenitally blind adults and sighted controls attended either to central or peripheral sound sources in

order to detect a rare noise burst either at the 0- or the 90-degree loudspeaker (on different blocks). Behavioral data revealed a higher spatial resolution in the blind, particularly when they were attending to the periphery. Gradients of ERP amplitudes suggested a sharper auditory spatial attention focus in the blind compared to the sighted for peripheral sounds. The results suggest that across auditory and visual modalities the representation of peripheral space is more altered by early sensory experience than is the representation of central space. It is interesting that, on close examination of the behavioral data presented in Rice (1965) on blind humans and Rauschecker and Kneipert (1993) on blind cats, a similar effect is observed—i.e., an advantage in sound localization for the blind that is largest at peripheral locations.

Developmental specificity of language functions in human

It is reasonable to assume that the rules and principles that govern the development of the sensory systems also guide the development of language-relevant brain systems. Thus, differences in the rate of differentiation and degree of specification may be apparent within language and help to identify different functional subsystems. In a series of experiments we have studied the development of the neural systems important in lexical semantic and grammatical processing. In normal, right-handed, monolingual adults nouns and verbs (“open-class” words) that provide lexical/semantic information elicit a different pattern of brain activity (as measured by ERPs) than do function words including prepositions and conjunctions (“closed-class” words) that provide grammatical information in English (Neville, Mills, and Lawson, 1992; Nobre and McCarthy, 1994). In addition, sentences that are semantically nonsensical (but grammatically intact) elicit a different pattern of ERPs than do sentences that contain a violation of syntactic structure (but leave the meaning intact) (Neville et al., 1991; Osterhout, McLaughlin, and Bersick, 1997). These results are consistent with several other types of evidence suggesting that different neural systems mediate the processing of lexical/semantic and grammatical information in adults. Specifically, they imply a greater role for more posterior temporal-parietal systems in lexical/semantic processing and for frontal-temporal systems within the left hemisphere in grammatical processing. This overall pattern appears ubiquitous in adults, and many investigators have suggested that the central role of the left hemisphere in language processing is strongly genetically determined. Certainly, the fact that most individuals, regardless of the language they learn, display left-hemisphere dominance for that language indicates that

this aspect of neural development is strongly biased. Nonetheless, it is likely that language-relevant aspects of cerebral organization are dependent on and modified by language experience. Many investigators have studied this question by comparing cerebral organization in individuals who learned a second language at different times in development (Perani et al., 1996; Dehaene et al., 1997; Kim et al., 1997). In general, age of exposure to language appears to affect cerebral organization for that language. Moreover, there appears to be specificity in these effects: In Chinese-English bilinguals delays of as long as 16 years in exposure to English had very little effect on the organization of the brain systems active in lexical/semantic processing. In contrast, delays of just 4 years had significant effects on those aspects of brain organization linked to grammatical processing (figure 7.5; see color plate 2) (Weber-Fox and Neville, 1996). These results and parallel behavioral results from the same study suggest that aspects of semantic and grammatical processing differ markedly in the degree to which they depend upon language input. Specifically, grammatical processing appears more vulnerable to delays in language experience.

STUDIES OF DEAF ADULTS Further evidence on this point was provided by ERP studies of English sentence processing by congenitally deaf individuals who learned English late and as a second language (American Sign Language or ASL was the first language of these subjects; Neville, Mills, and Lawson, 1992). Deaf subjects displayed ERP responses to nouns and to semantically anomalous sentences in written English that were indistinguishable from those of normal hearing subjects who learned English as a first language. These data are consistent with the hypothesis that some aspects of lexical/semantic processing are largely unaffected by the many aspects of language experience that differ between normally hearing and congenitally deaf individuals. By contrast, deaf subjects displayed aberrant ERP responses to grammatical information like that presented in function words in English. Specifically, they did not display the specialization of the anterior regions of the left hemisphere characteristic of native hearing/speaking learners. These data suggest that the systems mediating the processing of grammatical information are more modifiable and vulnerable in response to altered language experience than are those associated with lexical/semantic processing.

STUDIES OF ASL Recently, we have employed the ERP and fMRI techniques to pursue this hypothesis further and also to obtain evidence on the question of whether the strongly biased role of the left hemisphere

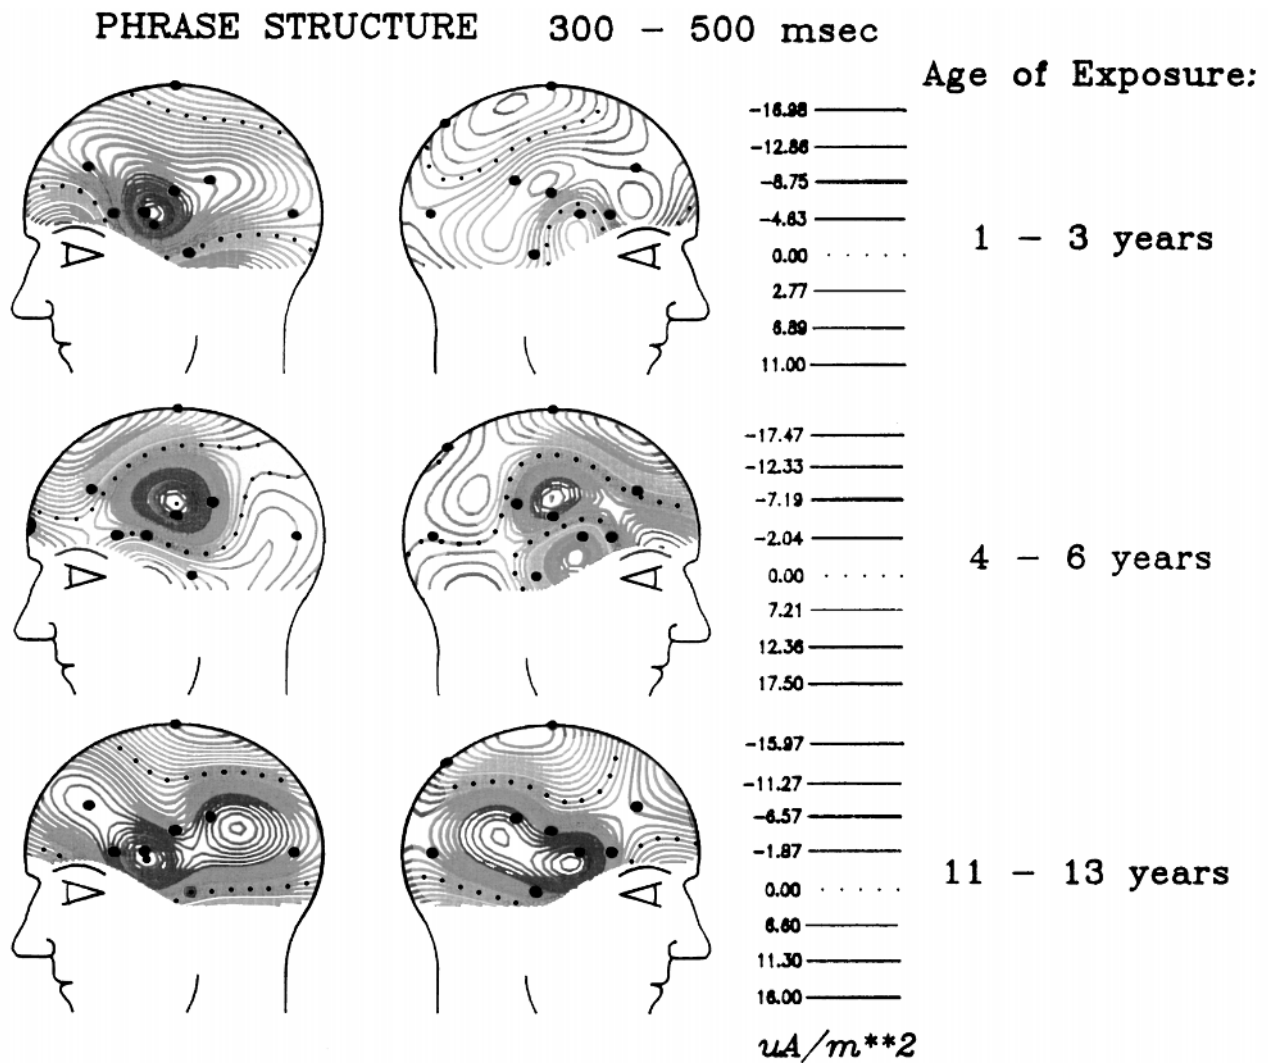

FIGURE 7.5 Current source density (CSD) analyses of responses to grammatical anomalies (violations of phrase structure) in English. Early learners of English (1–3 years) display a

left lateralized activation, but delays in age of exposure (4–13 years) are associated with bilateral activation.

in language occurs independently of the structure and modality of the language first acquired (Neville et al., 1997, 1998). ERPs recorded to response to open- and closed-class signs in ASL sentences displayed similar timing and anterior/posterior distributions to those observed in previous studies of English. But, whereas in native speakers of English responses to closed-class English words were largest over anterior regions of the left hemisphere, in native signers closed-class ASL signs elicited bilateral activity that extended posteriorly to include parietal regions of both the left and right hemispheres. These results imply that the acquisition of a language that relies on spatial contrasts and the perception of motion may result in the inclusion of right-hemisphere regions into the language system. As seen in figure 7.6, both hearing and deaf native signers displayed this effect. However, hearing people who ac-

quired ASL in the late teens did not show this effect, suggesting there may be a limited time (sensitive) period when this type of organization for grammatical processing can develop. By contrast, the response to semantic information was not affected by age of acquisition of ASL, in keeping with the results from studies of English suggesting that these different subsystems within language display different degrees of developmental plasticity.

In fMRI studies comparing sentence processing in English and ASL we also observed evidence for biological constraints and effects of experience on the mature organization of the language systems of the brain. As seen at the top of figure 7.7 (color plate 3), when hearing adults read English (their first language), there is robust activation within the left (but not the right) hemisphere and in particular within the inferior frontal (Broca's) regions.

FIGURE 76 ERPs to closed-class signs in ASL sentences from 10 deaf, 10 hearing native signers, and 10 late learners of ASL. Recordings from parietal areas of the right hemisphere.

When deaf people read English (their second language, learned late and imperfectly), we did not observe activation of these regions within the left hemisphere (figure 7.7, middle). Is the absence of left-hemisphere activation in the deaf linked to lack of auditory experience with language or to incomplete acquisition of the grammar of the language? ASL is not sound-based, but displays each of the characteristics of all formal languages including a complex grammar (that makes extensive use of spatial location and hand motion) (Klima and Bellugi, 1979). Studies of the same deaf subjects when viewing sentences in their native ASL clearly show activation within the same inferior frontal regions of the left hemisphere that are active when native speakers of English process English (figure 7.7, bottom). These data suggest a strong biological bias for these neural systems to mediate grammatical language regardless of the structure and modality of the language acquired. However, if the language is not acquired within the appropriate time window, this strong bias is not expressed. Biological constraints and language experience interact epigenetically, as has been described for many other systems described in developmental biology.

The fMRI data also indicate a robust role for the right hemisphere in processing ASL. These results suggest that the nature of the language input, in this case the co-occurrence of location and motion information with language, shapes the organization of the language systems of the brain. Further research is necessary to specify the different times in human development when particular types of input are required for optimal development of the many systems and subsystems important in language processing.

EFFECTS OF PRIMARY LANGUAGE ACQUISITION ON CEREBRAL ORGANIZATION The research summarized above implies that language experience determines the development and organization of language-relevant systems of the brain. A strong test of this hypothesis would be to chart the changes in brain organization as children acquire primary language, and to separate these from more general maturational changes (Mills, Coffey-Corina, and Neville, 1993, 1997; Neville and Mills, 1997). We compared patterns of neural activity relevant to language processing in 13- and 20-month-old infants to determine whether or not changes in cerebral organization occur as a function of specific changes in language development when chronological age is held constant. ERPs were recorded as children listened to a series of words whose meaning was understood by the child, words whose meaning the child did not understand, and backward words. Specific and different ERP components discriminated comprehended words from unknown and from backward words. Distinct lateral and anterior-posterior specializations were apparent in ERP responses to the different types of words. At 13 months of age the effects of word comprehension were apparent over anterior and posterior regions of both the left and right hemispheres. However, at 20 months of age the effects occurred only over temporal and parietal regions of the left hemisphere. This increasing specialization of language-relevant systems is not, however, solely dependent on chronological age. In comparisons of children of the same age who differ in size of vocabulary it is clear that language experience/knowledge is strongly predictive of the maturity of cerebral organization: 13-month-

FIGURE 7.7 Cortical areas showing increases in blood oxygenation on fMRI when normal hearing adults read English sentences (top), when congenitally deaf native signers read En-

glish sentences (middle), and when congenitally deaf native signers view sentences in their native sign language (American Sign Language).

old infants with large vocabularies also display more focal left temporal/parietal effects of word meaning than do those with small vocabularies.

A similar effect is found in the development of the differential processing of open- and closed-class words. We compared ERPs to open- and closed-class words in infants and young children from 20 to 42 months of age. All children understood and produced both the open- and closed-class words presented. At 20 months, ERPs in response to open- and closed-class words did not differ. However, both types of words elicited ERPs that differed from those elicited by unknown and backward words. These data suggest that in the earliest stages of language development, when children are typically speaking in single-word utterances or beginning to put two words together, open- and closed-class words elicit similar patterns of brain activity. At 28–30 months of age, when children typically begin to speak in short phrases, ERPs to open- and closed-class words elicited

different patterns of brain activity. However, the more mature left-hemisphere asymmetry to closed-class words was not observed. By 3 years of age most children speak in sentences and use closed-class words appropriately to specify grammatical relations and, like adults, ERPs from 3-year-olds displayed a left-hemisphere asymmetry to closed-class words. Figure 7.8 (color plate 4) illustrates the development of the left-hemisphere asymmetry to closed-class words in current source density maps across the three age groups. The results across the three groups are consistent with the hypothesis that, initially, open- and closed-class words are processed by similar brain systems, and that these systems become progressively specialized with increasing language experience. Further evidence on this hypothesis comes from an examination of ERPs from children who were the same age but differed in language abilities. The 20-month-old children who scored below the 50th percentile for vocabulary size did not show ERP differences to open- and closed-

CLOSED CLASS WORDS

20 month olds

28-30 month olds

36-42 month olds

FIGURE 7.8 Current source density (CSD) analyses of neural activity to closed-class words at 200 ms. The CSDs illustrate sinks [i.e., activity flowing into the head (purple)] and sources [i.e., activity flowing out of the head (orange)] at three age groups. Top: At 20 months the CSD shows sinks over both the

left and the right hemispheres. Middle: At 28–30 months the CSD shows sinks that are bilateral but slightly more prominent over the right than the left hemisphere. Bottom: At 36–42 months the CSD shows a sink over left anterior regions.

class words. In contrast, those above the 50th percentile displayed ERP differences to open- and closed-class words that were similar to the patterns shown in 28–30-month-olds. These data strongly suggest that the organization of brain activity is linked to language abilities rather than to chronological age per se.

Summary and conclusions

The results from the language studies, taken as a whole, point to different developmental time courses and developmental vulnerabilities of aspects of grammatical and semantic/lexical processing. They thus provide support for conceptions of language that distinguish these subprocesses within language. Similarly, following auditory deprivation, processes associated with the dorsal visual pathway were more altered than were functions associated with the ventral pathway, providing support for conceptions of visual system organization that distinguish functions along these lines. A general hypothesis that may account for the different patterns of plasticity within both vision and language is that systems employing fundamentally different learning mechanisms display different patterns of developmental plasticity. It may be that systems displaying experience-dependent change throughout life—including the topography of sensory maps (Merzenich et al., 1988; Gilbert, 1995; Kaas, 1995), lexical acquisition (i.e., object–word associations), and the establishment of form, face, and object representations (i.e. ventral pathway functions)—rely upon very general, associative learning mechanisms that permit learning and adaptation throughout life. By contrast, systems important for computing dynamically shifting relations between locations, objects, and events (including the dorsal visual pathway and the systems of the brain that mediate grammar) appear dependent on and modifiable by experience primarily during more limited periods in development. This could account both for the greater developmental deficits and enhancements of dorsal pathway function following various developmental anomalies and for the greater effects of altered language experience on grammatical functions. Further research is necessary to characterize systems that become constrained in this way and those that can be modified throughout life. This type of developmental evidence can contribute to fundamental descriptions of the architecture of different cognitive systems. Additionally, in the long run, they may contribute to the design of educational and habilitative programs for both normally and abnormally developing children.

ACKNOWLEDGMENTS This research has been supported by grants from National Institutes of Health, DC00128, and

DC00481. We are grateful to our many collaborators on the several studies summarized here, and to Linda Heidenreich for manuscript preparation. We thank Jeff Goodhill for his careful reading of this manuscript.

Language, Mind, and Brain: Experience Alters Perception

PATRICIA K. KUHL

ABSTRACT How does one individual acquire a specific language? Is it appropriate to call it “learning” in the traditional sense? Historically, two dramatically opposed views formed the cornerstones of the debate on language. In one view, a universal grammar and phonology are innately provided and input serves to trigger the appropriate version. In the other view, no innate knowledge is provided and language is acquired through a process of external feedback and reinforcement. Both theories are based on assumptions about the nature of language input to the child and the nature of the developmental change induced by input. New data reviewed here, showing the effects of early language experience on infants, suggest a theoretical revision. By one year of age, prior to the time infants begin to master higher levels of language, infants’ perceptual and perceptual-motor systems have been altered by linguistic experience. Phonetic perception has changed dramatically to conform to the native-language pattern, and language-specific speech production has emerged. According to the model described here, this developmental change is caused by a complex “mapping” of linguistic input. This account is different in two respects from traditional views: (1) Language input is not conceived of as triggering innately provided options; (2) the kind of developmental change that occurs does not involve traditional Skinnerian learning, in which change is brought about through reinforcement contingencies. The consequences of this are described in a developmental theory at the phonetic level that may apply to higher levels of language.

Nature, nurture, and a historical debate

Forty-one years ago, a historic confrontation occurred between a strong nativist and a strong learning theorist. Chomsky’s (1957) reply to Skinner’s (1957) *Verbal Behavior* had just been published, re-igniting the debate on the nature of language. In Chomsky’s (1965, 1981) nativist view, universal rules encompassing the grammars and phonologies of all languages were innately specified. Language input served to “trigger” the appropriate subset of rules, and developmental change in language ability was viewed as biological growth akin to that of bodily organs, rather than learning. In the Skinnerian view, language was explicitly learned. Language was brought about in the child through a process of explicit

feedback and external control of reinforcement contingencies (Skinner, 1957).

Both views made assumptions about three critical parameters: (1) the biological preparation that infants bring to the task of language learning, (2) the nature of language input, and (3) the nature of developmental change. Chomsky asserted, through the “poverty of the stimulus” argument, that language input to the child is greatly underspecified. Critical elements are missing, hence the necessity for innately specified information. Skinner viewed speech as simply another operant behavior, shaped through parental feedback and reinforcement like all other behaviors.

In the decades that have passed since these positions were developed, the debate has been played out for language at the syntactic, semantic, and phonological levels. In this chapter, I concentrate primarily on the phonetic level of language, using the elementary components of sounds—the consonants and vowels that make up words—to structure an argument about what is given by nature and gained by experience in the acquisition of language. Studying the sound structure of language allows us to test the perception of language in infants just hours old, addressing the question of what language capacities are innate in infants. Then, by tracking the development of infants raised in various cultures listening to different languages, we can determine, again using tests of perception, when infants begin to diverge as a function of experience with a particular language. These methods provide a strong test of the historically opposing views, and the results of these tests deliver dramatic evidence of the interaction between biology and culture, leading to a new view.

Origins of conceptual distinctions and the modern view

The discussion among linguists and psychologists regarding language is only one forum in which the nature–nurture issue has been debated. Begun by philosophers hundreds of years ago, the nativism–empiricism debate or the nativist–constructivist debate

PATRICIA K. KUHL Department of Speech and Hearing Sciences, University of Washington, Seattle, Wash.

concerned the origins of knowledge and whether it stemmed from native abilities or was empirically derived. The debate is of continuing interest across a wide variety of disciplines: ethology (Bateson, 1991; Hauser, 1997), neuroscience (Carew, Menzel, and Shatz, 1998), language science (Kuhl, 1994, 1998a; Pinker, 1994), and developmental psychology (Bates and Elman, 1996; Carey, 1985; Gopnik and Meltzoff, 1997; Karmiloff-Smith, 1995).

These groups use different terms to distinguish complex behaviors that appear relatively immune to, as opposed to wholly dependent on, experience. The terminology reflects differences in emphasis between groups. In ethology for example, the distinction has traditionally been drawn between *innate* or *instinctual* behaviors, considered to be genetically determined, and those *learned* as a function of exposure to the environment (Lorenz, 1965; Thorpe, 1959; Tinbergen, 1951). The emphasis in early ethological writings was on explaining behaviors that existed at birth in the absence of experience (Lorenz’s “innate release mechanisms”).

In the early psychological literature on the mental development of the child (James, 1890; Koffka, 1924; Vygotsky, 1962), and also in the neuroscience literature (Cajal, 1906), the distinction was drawn using the terms “development” and “learning.” *Development* included changes in the organism over time that depend primarily on maturation or internal factors leading to the expression of information specified in the genome. The term development and the term innate are therefore similar, but not identical. *Development* (as opposed to *innate*) emphasized complex behaviors, thought to be un-

der genetic control, that unfold well after birth rather than those existing at birth (innate behavior). *Learning* encompassed processes that depend on explicit experience and produce long-lasting changes. Neuroscientists currently debate how experience alters the brain and whether experience induces *selection*, where options are chosen from a set of innate possibilities, or *instruction*, where experience sculpts a wide open brain (see Doupe and Kuhl’s 1999 discussion of birdsong and speech).

Modern writers in all the aforementioned fields agree that behavior unfolds under the control of both a genetic blueprint and the environment, and that the debate now centers on the precise nature of the interplay between the two. Using the development/learning terminology, four alternative models—A through D—can be conceptualized, as illustrated in figure 8.1. The first two are not interactionist accounts, whereas the last two can be described in this way.

Development and learning can be thought of as completely separable processes (figure 8.1, model A). Development follows a maturational course guided by a genetic blueprint, and learning neither follows from nor leads to changes in the pre-established course of development. Alternatively, they can be thought of as two processes so inseparable that they cannot be pulled apart, even conceptually (figure 8.1, model B).

More commonly, development and learning are thought of as separate and distinguishable processes that interact in one way or another (figure 8.1, models C and D). Developmental psychologists, neuroscientists, and neurobiologists largely agree that the interactionist view is the correct one (Bates and Elman, 1996; Bonhoeffer

Conceptual relations between development and learning

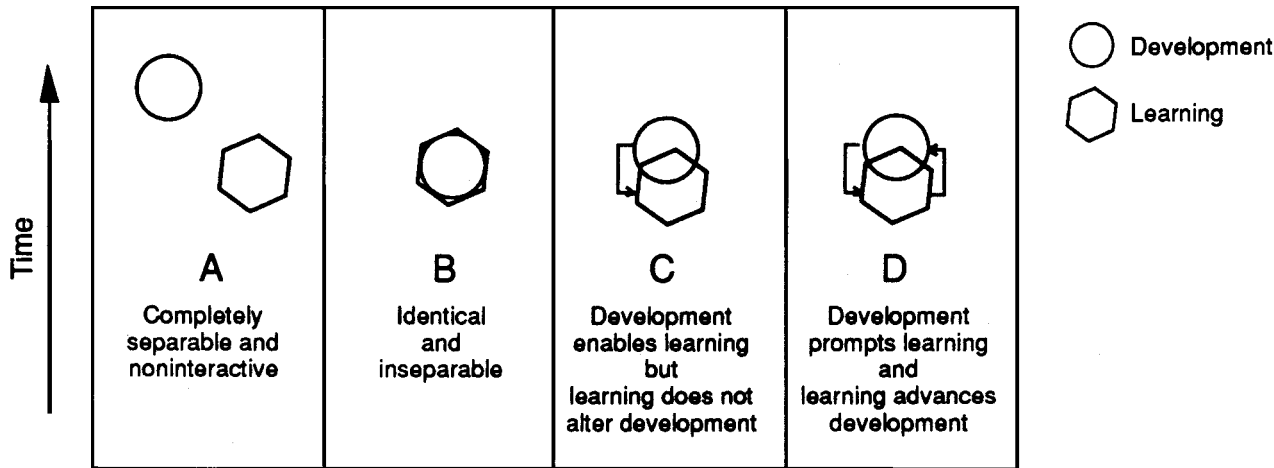

FIGURE 8.1 Conceptual relations between development and learning.

and Shatz, 1998; Carey, 1985; Doupe, 1998; Doupe and Kuhl, 1999; Fanselow and Rudy, 1998; Gopnik and Meltzoff, 1997; Karmiloff-Smith, 1995; Kuhl, 1994, 1998a; Marler, 1990). At issue, however, is exactly how the two systems interact, and particularly whether the interaction between development and learning is bidirectional.

Among the interactionist views, one model is that development enables learning, but that learning does not change the course of development, which unfolds more or less on its own timetable (figure 8.1, model C). Learning is seen as capitalizing on the achievements of development, and cannot occur unless a certain level of development has been achieved. The interaction is unidirectional, however. Development is not affected by learning. In classical developmental psychology, this position is closest to the view of Piaget (1954). In modern neurobiology, the notion that there are “constraints” on learning, that development both prepares the organism and sets limits on learning, is consistent with this model (see Marler, 1974, and Doupe, 1998, for the case of bird-song). Greenough and Black’s (1992) “experience-expectant” plasticity, wherein changes in neural development are thought to precede and prepare an organism to react to a reliably present environmental stimulus, provides a detailed example of this model. In each of these cases, development is conceived of as both enabling and limiting learning, but learning does not alter the course of development.

There is an alternative interactionist view. This model describes development and learning as mutually affecting one another (figure 8.1, model D). Development enables and even prompts learning, and learning in turn advances development. This view is closest to that developed by Vygotsky (1979). Vygotsky’s theory, the “zone of proximal development” (ZPD), described development at two levels. One was the infant’s actual developmental level, the level already achieved. The second was the level that was just within reach. The ZPD was the difference between the two. In Vygotsky’s view, environmental stimulation slightly in advance of current development (in the ZPD) resulted in learning and, when this occurred, learning prompted development. Recent theories proposed by developmental psychologists to account for a wide variety of cognitive and linguistic tasks converge on the point that there is mutual interaction between development and learning (Carey, 1985; Gopnik and Meltzoff, 1997; Karmiloff-Smith, 1991).

In linguistic theory, Chomsky’s classic view that the growth of language is largely determined by a maturational process fits model C. Experience plays a role, but it is seen as triggering prespecified options or as setting

innately determined parameters (Chomsky, 1981). The data reviewed here at the phonetic level of language come closer to the mutual interaction of model D. In the model of speech development I describe, language input plays more than a triggering role in the process. Language input is mapped in a complex process that appears to code its subtle details. Input thus goes beyond setting the parameters of prespecified options. Moreover, early mapping of the perceptual regularities of language input is argued to allow infants to recognize words and phrases, thus advancing development.

In summary, there is a great deal of support for interactionist views (models C and D) over noninteractionist views (models A and B). While the relations between learning and development may differ across species and systems, there is an emerging consensus across diverse disciplines (including neurobiology, psychology, linguistics, and neuroscience) that development and learning are not independent entities. Speech falls clearly on the interactionist side. However, the form of the interaction remains a question, with a cutting-edge issue being whether (and how) learning can alter development. The model proposed here on the basis of recent research on speech development goes some distance toward addressing this issue.

Explanations for developmental change in speech

One of the puzzles in language development is to explain the orderly transitions that all infants go through during development. Infants the world over achieve certain milestones in linguistic development at roughly the same time, regardless of the language they are exposed to. Moreover, developmental change can also include cases in which infants’ early skills exceed their later ones. Explaining these transitions is one of the major goals of developmental linguistic theory.

One of these transitions occurs in speech perception. At birth, infants discern differences between all the phonetic units used in the world’s languages (Eimas, Miller, and Jusczyk, 1987). All infants show these universal skills, regardless of the language environment in which they are being raised. Data on nonhuman animals’ perception of speech suggest that the ability to partition the basic building blocks of speech is deeply rooted in our evolutionary history (Kuhl, 1991a).

When do infants from different cultures begin to diverge? Infants’ initial language-universal perceptual abilities are highly constrained just one year later. By the end of the first year, infants fail to discriminate foreign language contrasts they once discriminated (Werker and Tees, 1984), resembling the adult pattern. Adults often find it difficult to perceive differences

between sounds not used to distinguish words in their native language. Adult native speakers of Japanese, for example, have great difficulty discriminating American English /r/ and /l/ (Strange, 1995; Best, 1993), and American English listeners have great difficulty hearing the difference between Spanish /b/ and /p/ (Abramson and Lisker, 1970).

Infants' abilities change dramatically over a 6-month period. A recent study completed in Japan shows, for example, that at 6 months Japanese infants respond to the /r-l/ distinction and are as accurate in perceiving it as American 6-month-old infants. By 12 months, Japanese infants no longer demonstrate this ability, even though American infants at that same age have become much better at discriminating the two sounds (Kuhl, Kir-tani, et al., 1997).

A similar transition occurs in speech production. Regardless of culture, all infants show a universal progression in the development of speech which encompasses five distinct phases: *Cooing* (1 to 4 months), in which infants produce sounds that resemble vowels; *Canonical Babbling* (5 to 10 months), during which infants produce strings of consonant-vowel syllables, such as "baba-baba" or "mamamama"; *First Words* (10 to 15 months), wherein infants use a consistent phonetic form to refer to an object; *Two Word Utterances* (18 to 24 months), in which two words are combined in a meaningful way; and *Meaningful Speech* (15 months and beyond), in which infants produce both babbling and meaningful speech to produce long intonated utterances (Ferguson, Menn, and Stoel-Gammon, 1992). Interestingly, deaf infants exposed to a natural sign language, such as American Sign Language (ASL), are purported to follow the same progression using a visual-manual mode of communication (Petitto, 1993).

While infants across cultures begin life producing a universal set of utterances that cannot be distinguished, their utterances soon begin to diverge, reflecting the influence of the ambient language. By the end of the first year, the utterances of infants reared in different countries begin to be separable; infants show distinct patterns of speech production, both in the prosodic (intonational patterns) and phonetic aspects of language, that are unique to the culture in which they are being raised (de Boysson-Bardies, 1993). In adulthood, the distinctive speech motor patterns initially learned contribute to "accents" in speaking another language (Flege, 1988).

The transition in speech perception and production from a pattern that is initially universal across languages to one that is highly specific to a particular language presents one of the most intriguing problems in language acquisition: What causes the transition? We know it is

not simply maturational change. In the absence of natural language input, as in the case of socially isolated children (Fromkin et al., 1974; Curtiss, 1977) or cases in which abandoned children were raised quite literally in the wild (Lane, 1976), full-blown linguistic skills do not develop. Linguistic input and social interaction provided early in life appear to be necessary.

The thesis developed here, using the phonetic level, is that linguistic experience produces a special kind of developmental change. Language input alters the brain's processing of the signal, resulting in the creation of complex mental maps. The mapping "warps" underlying dimensions, altering perception in a way that highlights distinctive categories. This mapping is not like traditional psychological learning. In the psychological literature, for example, this kind of learning depends on the presence of specific contingencies that reward certain responses, feedback about the correctness of the response, and step-by-step shaping of the response (Skinner, 1957). The kind of learning reflected in language is very different. While it depends on external information from the environment (language input), it requires neither explicit teaching nor reinforcement contingencies. Given exposure to language in a normal and socially interactive environment, language learning occurs; and the knowledge gained about a specific language is long-lasting and difficult to undo.

Language experience alters perception

The thesis developed here for the phonetic level of language is that ambient language experience produces a "mapping" that alters perception. A research finding that helps explain how this occurs is called the "perceptual magnet effect." It is observed when tokens perceived as exceptionally good representatives of a phonetic category (prototypes) are used in tests of speech perception (Kuhl, 1991b). The notion that categories have prototypes stems from cognitive psychology. Findings in that field show that the members of common categories (like the category bird or dog) are not equal: An ostrich is not as representative of the category bird as a robin; a terrier is not as representative of the category dog as a collie. These prototypes, or best instances of categories, are easier to remember, show shorter reaction times when identified, and are often preferred in tests that tap our favorite instances of categories (Rosch, 1977). This literature motivated us to test the concept that phonetic categories had prototypes, or best instances, in the early 1980s.

Our results demonstrated that phonetic prototypes did exist (Grieser and Kuhl, 1989; Kuhl, 1991b), that they differed in speakers of different languages (Kuhl,

1992; Näätänen et al., 1997; Willerman and Kuhl, 1996), and that phonetic prototypes function like perceptual magnets for other sounds in the category (Kuhl, 1991b). When listeners hear a phonetic prototype and attempt to discriminate it from sounds that surround it in acoustic space, the prototype displays an attractor effect on the surrounding sounds (figure 8.2). It perceptually pulls other members of the category toward it, making it difficult to hear differences between the prototype and surrounding stimuli. Poor instances from the category (nonprototypes) do not function in this way. A variety of experimental tasks produced this result with both consonants and vowels (Iverson and Kuhl, 1995, 1996; Sussman and Lauckner-Morano, 1995). Other studies confirm listeners' skills in identifying phonetic prototypes and show that they are language specific (Kuhl, 1992; Miller, 1994; Willerman and Kuhl, 1996).

Developmental tests revealed that the perceptual magnet effect was exhibited by 6-month-old infants for the sounds of their native language (Kuhl, 1991b). In later studies, cross-language experiments suggest that the magnet effect is the product of linguistic experience (Kuhl et al., 1992). In the cross-language experiment, infants in the United States and Sweden were tested. The infants from both countries were tested with two vowel prototypes, an American English vowel prototype, /i/ (as in "peep"), and a Swedish vowel prototype, /y/ (as in "fye"). The results demonstrated that the perceptual magnet effect in 6-month-old infants was influenced by exposure to a particular language. American infants demonstrated the magnet effect only for the American English /i/; they treated the Swedish /y/ as a nonprototype. Swedish infants showed the opposite pattern, demonstrating the magnet effect for the Swedish /y/ and treating the American English /i/ as a nonprototype. This is the youngest age at which language experience has been shown to affect phonetic perception.

The perceptual magnet effect thus occurs prior to word learning. What this means is that in the absence of formal language understanding or use—before infants utter or understand their first words—infants' perceptual systems strongly conform to the characteristics of the ambient language. We previously believed that word learning caused infants to recognize that phonetic changes they could hear, such as the change that Japanese infants perceived between /r/ and /l/, did not change the meaning of a word in their language. This discovery was thought to cause the change in phonetic perception. We now know that just the opposite is true. Language input sculpts the brain to create a perceptual system that highlights the contrasts used in the language, while de-emphasizing those that do not, and this happens prior to word learning. The change in phonetic perception thus assists word learning, rather than the reverse.

Further tests on adults suggested that the magnet effect distorted perception to highlight sound contrasts in the native language. Studies on the perception of the phonetic units /r/ and /l/, as in the words "rake" and "lake," illustrate this point. The /r-l/ distinction is one notoriously difficult for Japanese speakers, and our studies sought to determine how adults from different cultures perceive these two sounds. To conduct the study, we used computer-synthesized syllables beginning with /r/ and /l/, spacing them at equal physical intervals in a two-dimensional acoustic grid (Iverson and Kuhl, 1996) (figure 8.3A). American listeners identified each syllable as beginning with either /r/ or /l/, rated its category goodness, and estimated the perceived similarity for all possible pairs of stimuli using a scale from "1" (very dissimilar) to "7" (very similar). Similarity ratings were scaled using multidimensional scaling (MDS) techniques. The results provide a map that indicates perceived distance between stimuli. The results revealed that perception distorts physical space. The physical

FIGURE 8.2 The perceptual magnet effect. When a variety of sounds in a category surround the category prototype (A), they are perceptually drawn toward the prototype (B). The proto-

type appears to function like a magnet for other stimuli in the category.

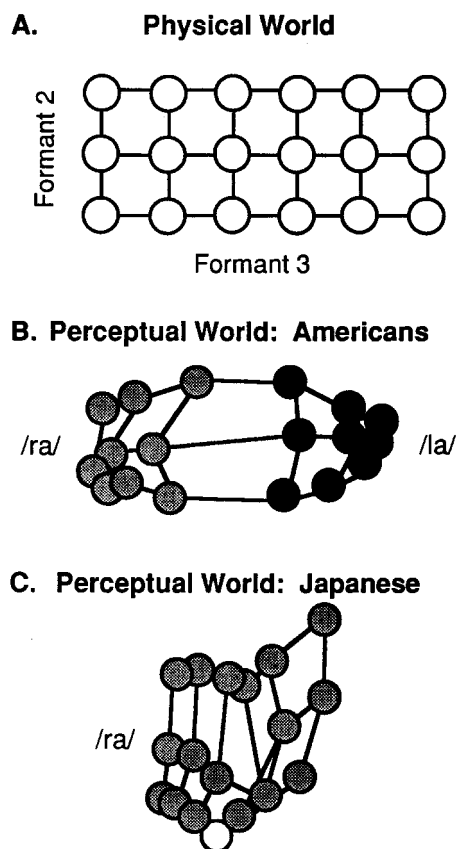

FIGURE 8.3 Physical (acoustic) versus perceptual distance. Consonant tokens of /r/ and /l/ were generated to be equally distant from one another in acoustic space (A). However, American listeners perceive perceptual space as shrunk near the best instances of /r/ (gray dots) and /l/ (black dots) and stretched at the boundary between the two (B). Japanese listeners' perceptual world differs dramatically; neither magnet effects nor a boundary between the two categories are seen (C).

(acoustic) differences between pairs of stimuli were equal; however, perceived distance was “warped” (figure 8.3B). The perceptual space around the best /r/ and the best /l/ was greatly reduced for American listeners, as predicted by the perceptual magnet effect, while the space near the boundary between the two categories was expanded.

This experiment has now been done using Japanese monolingual listeners (Kuhl et al., submitted) and the results show a strong contrast in the way the /r-l/ stimuli are perceived by American and Japanese adults (figure 8.3C). Japanese adults hear almost all the sounds as /r/; there is no /l/ in Japanese. More striking is the complete absence of these magnet and boundary effects in the Japanese MDS solution. The results suggest that linguistic experience forms perceptual maps specifying the perceived distances between speech stimuli, and that these maps differ greatly in people of different cultures.

The critical point for theory is that neither group perceives physical reality, the actual physical differences between sounds. For each language group, experience has altered perception to create a language-specific map of auditory similarities and differences. The map highlights sound contrasts of the speaker's native language by increasing internal category cohesion and maximizing the difference between categories.

The theoretical position developed here is that speech maps are developed early in infancy, prior to the development of word acquisition. The mapping of phonetic information is seen as enabling infants to recognize word candidates. For example, our work shows that Japanese infants fail to discriminate American English /r/ from /l/ at 12 months of age, though they did so perfectly well at 6 months of age (Kuhl, Andruski, et al., 1997). This would assist Japanese infants in word recognition by collapsing /r/- and /l/-like sounds into a single category, making it possible for Japanese infants to perceive their parents' productions of these sounds as one entity at 12 months, when the process of word acquisition begins. If they did not do so, it would presumably make it more difficult to map sound patterns onto objects and events. Mental maps for speech are the front end of the language mechanism. They point infants in the direction needed to focus on the aspects of the acoustic signal that will separate categories in their own native language. They provide a kind of attentional network that may function as a highly tuned filter for language. Such a network would promote semantic and syntactic analysis.

The view that phonetic mapping supports the recognition of higher order units is supported by data showing that slightly later in development infants use information about phonetic units to recognize word-like forms. Work by Jusczyk and his colleagues shows that just prior to word learning, infants prefer word forms that are typical of the native language, ones in which the stress patterns and phoneme combinations conform to the native-language pattern (Jusczyk et al., 1993). At about this age, infants have also been shown capable of learning the statistical probabilities of sound combinations contained in artificial words (Saffran, Aslin, and Newport, 1996). Infants' mapping at the phonetic level is thus seen as assisting infants in chunking the sound stream into higher order units, suggesting that “learning” promotes “development.”

The form of learning we are describing is different from historical versions of learning described by psychologists. It does not involve external reinforcement and contingency learning, as in Skinner. It is automatic and unconscious. During the first year of life, infants come to recognize the recurring properties of their na-

tive language and mentally store those properties in some form. Uncovering the underlying neural mechanisms that control this kind of learning may aid our general understanding of the kind of learning that makes us unique as a species.

A theory of speech development

Given these findings, how do we reconceptualize infants' innate predispositions as preparing them for experience? One view can be summarized as a three-step model of speech development, called the Native Language Magnet (NLM) model (Kuhl, 1994, 1998a). NLM describes infants' initial state as well as changes brought about by experience with language (figure 8.4). The model demonstrates how infants' developing native-language speech representations might alter both speech perception and production. The same principles apply to both vowel and consonant perception, and the example developed here is for vowels.

Phase 1 describes infants' initial abilities. At birth, infants discriminate the phonetic distinctions of all lan-

guages of the world. This is illustrated by a hypothetical F1/F2 coordinate vowel space partitioned into categories (figure 8.4A). These divisions separate perceptually the vowels of all languages. According to NLM, infants' abilities to hear all the relevant differences at this stage do not depend on specific language experience. Infants discriminate language sounds they have never heard.

The boundaries shown in phase 1 initially structure perception in a phonetically relevant way. However, these predispositions seen in humans at birth are not likely to be due to a "language module." This notion is buttressed by the fact that nonhuman animals also show this phenomenon, displaying abilities that were once thought to be exclusively human (Kuhl and Miller, 1975, 1978; Kuhl, 1991a; see also Kluender, Diehl, and Killeen, 1987, and Dooling, Best, and Brown, 1995, for demonstrations of speech perception abilities in nonhumans). This has been interpreted as evidence that the evolution of speech capitalized on sound distinctions well separated by the auditory system (Kuhl, 1989, 1991a).

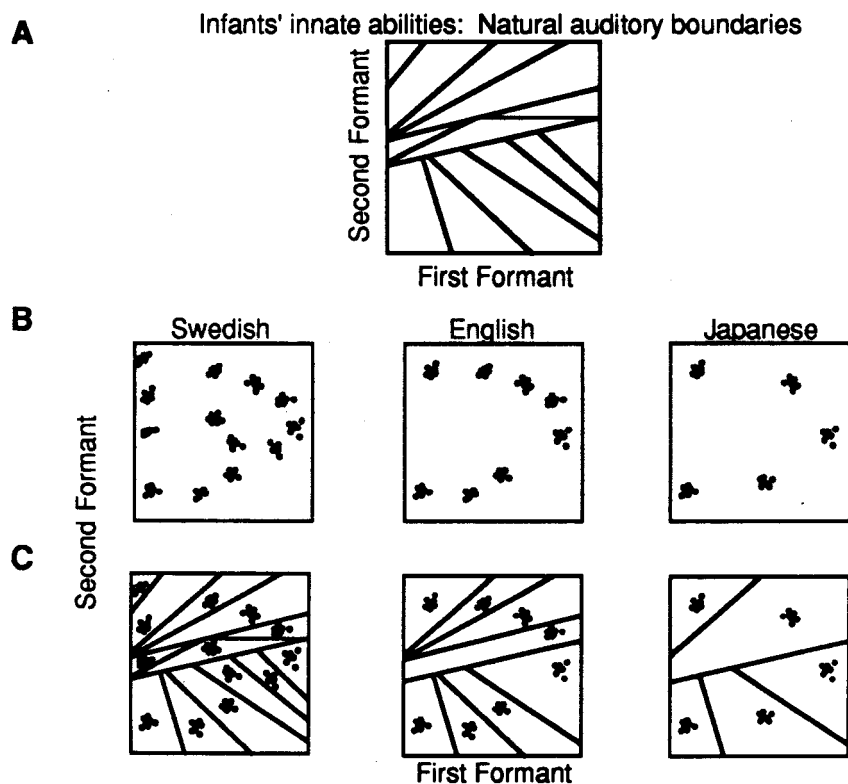

FIGURE 8.4 The native language magnet (NLM) model. (A) At birth, infants perceptually partition the acoustic space underlying phonetic distinctions in a language-universal way. They are capable of discriminating all phonetically relevant differences in the world's languages. (B) By 6 months of age, infants reared in different linguistic environments show an effect of language experience. Infants store incoming vowel informa-

tion in memory in some form. The resulting representations (shown by the dots) are language-specific, and reflect the distributional properties of vowels in the three different languages. (C) After language-specific magnet effects appear, some of the natural boundaries that existed at birth "disappear." Infants now fail to discriminate foreign-language contrasts they once discriminated.

Phase 2 describes the vowel space at 6 months of age for infants reared in three very different language environments, Swedish, English, and Japanese (figure 8.4B). By 6 months of age, infants show more than the ability to perceptually separate all phonetic categories, as shown in phase 1. The distributional properties of vowels heard by infants being raised in Sweden, America, and Japan differ. According to NLM, infants mentally represent this ambient language information (as shown in figure 8.4B), and their mental representations produce language-specific magnet effects. Thus, by 6 months, language-specific perceptual maps have begun to form.

Interesting questions about phase 2 magnet effects are: How much language input does it take to map speech in this way, and is all language heard by the child (including that from a radio or television) effective in producing this kind of learning? In fact, this was the question asked of me by President William J. Clinton at the White House Conference on “Early Learning and the Brain” in April of 1997. My answer was that at present we have no idea how much language input it takes to show these effects. Moreover, we do not know whether language from a disembodied source (TV, radio) would be sufficient to produce it. By 6 months of age, the earliest age for which we have evidence of magnet effects, our estimates suggest that infants have heard thousands of instances of vowels in *en face* communication with their parents (Kuhl, 1994), but that does not tell us what amount is necessary or whether TV is effective. These questions will require a great deal more work, and we have studies underway that will provide some interesting information.

Phase 3 shows how magnet effects recursively alter the initial state of speech perception, and affect the processing of foreign-language stimuli. Magnet effects cause certain perceptual distinctions to be minimized (those near the magnet attractors) while others are maximized (those near the boundaries between two magnets). The consequence is that some of the boundaries that initially divided the space disappear as the perceptual space is reconfigured to incorporate a language’s particular magnet placement (figure 8.4C). Magnet effects functionally erase certain boundaries—those relevant to foreign but not native languages. Listeners’ auditory systems still process the acoustic differences that separate categories, but their maps indicate that listeners no longer attend to these differences.

In Phase 3, a perceptual space once characterized by basic “auditory cuts”—boundaries that divide all speech categories, and ones demonstrated in nonhuman animals—has been replaced by a dramatically warped space dominated by magnet effects that completely restructure

the space. It is at this phase that infants fail to discriminate foreign-language contrasts that were once discriminable. The mapping of incoming speech has altered which stimulus differences infants respond to, producing a language-specific listener for the first time.

A natural question arising from these data is, what would happen to infants exposed to two different languages. The theory predicts that infants will develop magnet effects for the sound categories of both languages. Interestingly, preliminary data from studies underway suggest that development of two sets of magnet effects is particularly likely when the two languages are spoken by different speakers (mother speaks one language, father speaks another). Presumably, mapping two languages, each spoken by a different speaker, is made easier when infants can separate perceptually the maps for the two languages.

NLM theory offers an explanation for the developmental change observed in speech perception. A developing magnet pulls sounds that were once discriminable toward it, making them less discriminable. Magnet effects should therefore developmentally precede changes in infants’ perception of foreign-language contrasts; data indicate that they do (Werker and Polka, 1993). The magnet effect also helps account for the results of studies on the perception of sounds from a foreign language by adults (Best, 1993; Flege, 1993). For example, NLM theory may help explain Japanese listeners’ difficulty with American /r/ and /l/. The magnet effect for the Japanese /r/ category prototype (which is neither American /r/ nor /l/) will attract both /r/ and /l/, making the two sounds difficult for native-speaking Japanese people to discriminate (Kuhl et al., submitted). NLM theory argues that early experience establishes a complex perceptual network through which language passes. On this view, one’s primary language, and the map that results from early experience, will determine how other languages are perceived.

From a neuroscience perspective, it is of interest to ask whether the developmental change seen in infants’ perception of speech is *selective* or *instructive*. Neuroscientists are tempted to relate the finding that synaptic connections are overproduced and then pruned to the developmental time course seen in infants listening to speech, arguing that experience results in selection. But the comparison may not capture the essence of the process. If infants’ initial abilities, shared by animals, are simply due to general auditory perceptual mechanisms, while their eventual failures to discriminate are due to the attentional filters produced by magnet effects, what we have to explain physiologically is how the neural system codes these mental maps. The maps would appear to require instruction—some new neural entity sculpted

by experience. Could the development of mental maps be accounted for by physiological processes we now understand, such as synaptic pruning, or is something else needed? These questions will undoubtedly keep us busy for some time.

Reinterpreting “critical periods”

The interaction between genetic programming and environmental stimulation is nowhere more evident than in the literature on critical periods in learning (Thorpe, 1961; Marler, 1970). Critical periods are no longer viewed as strictly timed developmental processes with rigid cut-off periods that restrict learning to a specific time frame. Recent studies showing that learning can be stretched by a variety of factors have caused a shift in the terminology used to refer to this period. It is now understood that during “sensitive periods” exposure to specific kinds of information may be more effective than at other times, but that a variety of factors can alter the period of learning. Knudsen's work, for example, on the sound-localization system in the barn owl, shows that the sensitive period for learning the auditory-visual map in the optic tectum can be altered by a variety of factors that either shorten or extend the learning period; the learning period closes much earlier, for instance, if experience occurs in a more natural environment (Knudsen and Knudsen, 1990; Knudsen and Brainerd, 1995).

The idea that sensitive periods define “windows of opportunity” for learning, during which environmental stimulation is highly effective in producing developmental change, remains well supported both in the human and the animal literature. The ability to learn is not equivalent over time. The question is: What causes a decline in the ability to learn over the life span?

The sensitive period denotes a process of learning that is constrained primarily by time, or factors such as hormones, that are outside the learning process itself. There is an alternative possibility suggested by the studies on speech: Later learning may be limited by the fact that learning itself alters the brain, and the brain's resulting structure may produce a kind of interference effect that impacts later learning. For instance, if NLM's argument that learning involves the creation of mental maps for speech is true, this would mean that learning “commits” neural structure in some way. According to the model, speech processing is affected by this neural structure, and future learning is as well. The mechanisms governing an organism's general ability to learn may not have changed. Rather, initial learning may result in a structure that reflects environmental input and, once committed, the learned structure may interfere with the processing of information that does not conform to the

learned pattern. On this account, initial learning can alter future learning independent of a strictly timed period.

On this *interference* account, brain “plasticity” (ability to change) would be governed from a statistical standpoint. When additional input does not cause the overall statistical distribution to change substantially, the organism becomes less sensitive to input. Hypothetically, for instance, the infant's representation of the vowel /a/ might not change when the millionth token of the vowel /a/ is heard. Plasticity might thus be independent of time, but dependent on the amount and variability provided by experience. At some time in the life of an organism, one could conceive of a point beyond which new input no longer alters the underlying distribution, and this could, at least in principle, reduce the system's plasticity.

The interference view may account for some aspects of second language learning. When acquiring a second language, certain phonetic distinctions are notoriously difficult to master both in speech perception and production. Take the case of the /r-l/ distinction for native speakers of Japanese. Both hearing the distinction and producing it are very difficult for native speakers of Japanese (Goto, 1971; Miyawaki et al., 1975; Yamada and Tohkura, 1992). According to NLM, this is because exposure to Japanese early in life altered the Japanese infant's perceptual system, resulting in magnet effects for the Japanese phoneme /r/, but not for the American English /r/ or /l/. Once in place, Japanese magnet effects would not make it easy to process American English. American English /r/ and /l/ would be assimilated to Japanese /r/ (Kuhl et al., submitted).

A second language learned later in life (after puberty) may require separation between the two systems to avoid interference. Data gathered using fMRI techniques indicate that adult bilinguals who learned both languages early in life activate overlapping regions of the brain when processing the two languages, while those who learned the second language later activate two distinct regions of the brain for the two languages (Kim et al., 1997). This is consistent with the idea that the brain's processing of a primary language can interfere with the second language. This problem is avoided if both are learned early in development.

The general thesis is that acquiring new phonetic categories as adults is difficult because the brain's mental maps for speech, formed on the basis of the primary language, are incompatible with those required for the new language; hence, interference results. Early in life, interference effects are minimal and new categories can be acquired because input continues to revise the statistical distribution. As mentioned earlier, limited evidence

suggests that infants exposed to two languages do much better if each parent speaks one of the two languages than when both parents speak both languages. This may be because it is easier to map two different sets of phonetic categories (one for each of the two languages) if there is some way to keep them perceptually separate. Males and females produce speech in different frequency ranges, and this could make it easier to maintain separation.

These two factors—a maturationally defined temporal window governed by genetic factors, and the neural commitment that results from initial learning—could both be operating to produce constraints on learning a second language later in life. If a maturational process induces neural readiness at a particular time, input that misses this timing could reduce learning. At the same time, an interference factor produced by mapping language input might provide an independent mechanism that contributes to the difficulty in readily learning a second language in adulthood.

Vocal learning

Vocal learning—an organism’s dependence on auditory input both from itself and others to acquire a vocal repertoire—is not common among mammals, but is exhibited strikingly in songbirds (Marler 1990; Konishi, 1989). In certain songbirds, and in humans, young members of the species not only learn the perceptual properties of their conspecific communicative signals, but also become proficient producers of those signals. A great deal of research on birds (see Doupe, 1998, for review) and infants (Stoel-Gammon and Otomo, 1986; Oller et al., 1976) has shown that hearing the vocalizations of others, and hearing oneself produce sound, are both essential to the development of vocalizations. Deaf infants, for ex-

ample, do not babble normally (Oller and MacNeilage, 1983), nor do deafened birds (Konishi, 1965; Nottebohm, 1967). And infants tracheotomized at the time at which they would normally be babbling also results in abnormal patterns of development that persist (Locke and Pearson, 1990).

In the case of humans, speech motor patterns learned at the appropriate time become difficult to alter later in life. Speakers who learn a second language after puberty, for example, produce it with an accent typical of their primary language (Flege, 1993). Most speakers of a second language would like to speak like a native speaker, without an accent, but this is difficult to do, even with long-term instruction.

When do we adopt the indelible speech patterns that will mark us as native speakers of a particular language for our entire lives? Developmental studies suggest that by one year of age language-specific patterns of speech production appear in infants’ spontaneous utterances (de Boysson-Bardies, 1993; Vihman and de Boysson-Bardies, 1994). However, the fundamental capacity to reproduce the sound patterns one hears is in place much earlier. In a recent study, Kuhl and Meltzoff (1996) recorded infant utterances at 12, 16, and 20 weeks of age while the infants watched and listened to a video recording of a woman producing a vowel, /a/, /i/, or /u/. Infants watched the video for 5 minutes on each of three consecutive days. The results showed a developmental change in infants’ vowel productions between 12 and 20 weeks of age. The areas of vowel space occupied by infants’ /a/, /i/, and /u/ vowels become progressively more tightly clustered at each age, and by 20 weeks, a “vowel triangle” typical of that produced in every language of the world, had emerged in the infants’ own region of the vowel space (figure 8.5). This demonstrated that between 12 and 20 weeks of age, infants’ sound pro-

FIGURE 8.5 The location of /a/, /i/, and /u/ vowels produced by 12-, 16-, and 20-week-old infants. Infants’ vowel productions show progressively tighter clustering in vowel space over

the 8-week period and reflect differences between the three vowel categories seen in adults’ productions.

ductions were changing in a way that brought them closer to the adult pattern.

Direct evidence that infants were vocally imitating was also obtained in the study. By 20 weeks, infants were shown to reproduce the vowels they heard. Infants exposed to /a/ were more likely to produce /a/ than when exposed to either /i/ or /u/; similarly, infants exposed to either /i/ or /u/ were more likely to produce the vowel in that condition than when listening to either of the two alternate vowels. The total amount of exposure to a specific vowel in the laboratory was just 15 minutes; yet this was sufficient to influence infants' productions. If 15 minutes of laboratory exposure to a vowel is sufficient to influence infants' vocalizations, then listening to ambient language for weeks would be expected to provide a powerful influence on infants' production of speech. These data suggest that infants' stored representations of speech not only alter infant perception, but alter production as well, serving as auditory patterns that guide motor production. Stored representations are thus viewed as the common cause for both the tighter clustering observed in infant vowel production and the tighter clustering observed in infant vowel perception (figure 8.6).

This pattern of learning and self-organization, in which perceptual patterns stored in memory serve as guides for production, is strikingly similar for birdsong and speech (Doupe and Kuhl, 1999), in visual-motor learning in which such nonspeech oral movements as tongue protrusion and mouth opening are imitated

(Meltzoff and Moore, 1977, 1994), and in language involving both sign (Petitto and Marentette, 1991) and speech (Kuhl and Meltzoff, 1996). In each of these cases, perceptual experience establishes a representation that guides sensorimotor learning. In the case of infants and speech, perception affects production in the earliest stages of language learning, reinforcing the idea that the speech motor patterns of a specific language are formed very early in life. Once learned, motor patterns may also further development by altering the probability that infants will acquire words that contain items they are capable of producing.

The role of vision in speech perception

The link between perception and production can be seen in another experimental situation in speech, and there is some suggestion that this is mirrored in bird-song learning. Speech perception in adults is strongly affected by the sight of a talker's mouth movements during speech, indicating that our representational codes for speech contain both auditory and visual information. One of the most compelling examples of the polymodal nature of speech representations is auditory-visual illusions that result when discrepant information is sent to two separate modalities. One such illusion occurs when auditory information for /b/ is combined with visual information for /g/ (McGurk and MacDonald, 1976; Green et al., 1991; Kuhl et al., 1994; Massaro, 1987). Perceivers report the phenomenal

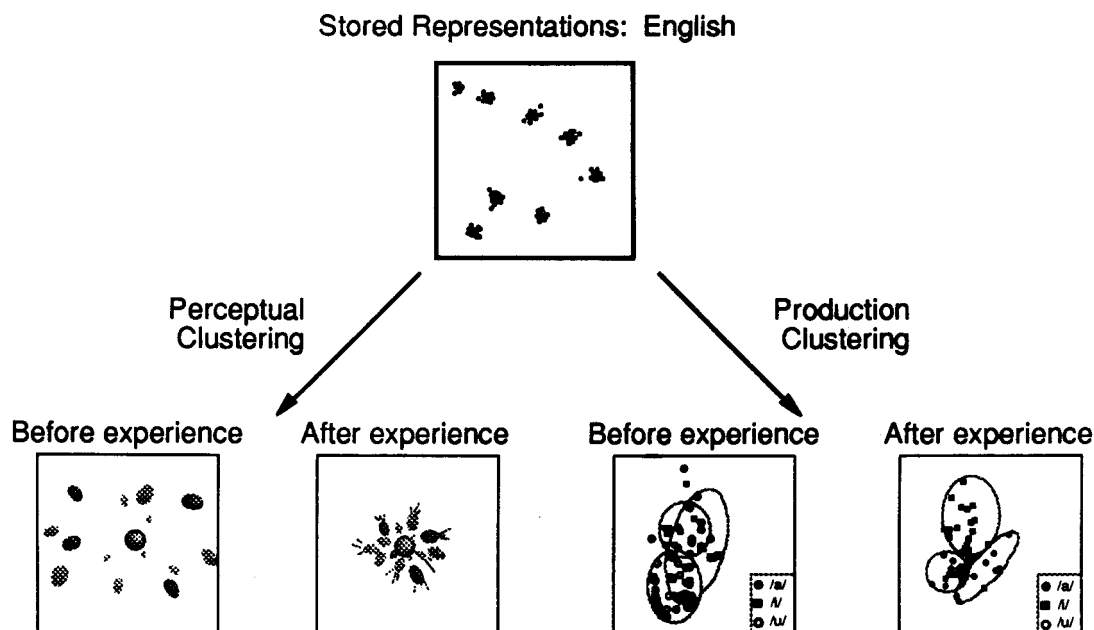

FIGURE 8.6 Stored representations of native-language speech affect both speech perception, producing the perceptual clustering evidenced by the magnet effect, as well as speech pro-

duction, producing the increased clustering seen in infants' vocalizations over time.

impression of an intermediate articulation (/da/ or /tha/) despite the fact that this information was not delivered by or to either sense modality. This is a very robust phenomenon and is readily obtained even when the information from the two modalities comes from different speakers, such as when a male voice is combined with a female face (Green et al., 1991). In this case, there is no doubt that the auditory and visual signals do not belong together. Yet the illusion is still unavoidable—our perceptual systems combine the multimodal information (auditory and visual) to give a unified percept.

Young infants are also affected by visual information. Infants just 18–20 weeks old recognize auditory-visual correspondences for speech, akin to what adults do when lipreading. In these studies, infants looked longer at a matching face—one pronouncing a vowel that matched the vowel sound they heard—than at a mismatched face (Kuhl and Meltzoff, 1982). Young infants demonstrate knowledge about both the auditory and visual information contained in speech, supporting the notion that infants’ stored speech representations contain information of both kinds. Additional demonstrations of auditory-visual speech perception in infants suggest that there is a left-hemisphere involvement in the process (MacKain et al., 1983), and more recent data by Rosenblum, Schmuckler, and Johnson (1997) and Walton and Bower (1993) suggest that the ability to match auditory and visual speech is present in newborns.

Visual information thus plays a very strong role in speech perception. When listeners watch the face of the talker, studies show that perception of the message is greatly enhanced, in effect contributing the equivalent of

a 20-dB boost (quite substantial) in the signal. This supports the view that speech in humans is polymodally represented, and that this is the case very early in development.

Nature of language input to the child

Research supports the idea that caretakers around the world use a near-universal speaking style when addressing infants and that infants prefer it over other complex acoustic signals (Fernald, 1985; Fernald and Kuhl, 1987). Estimates indicate that a typical listening day for a 2-year-old includes 20,000–40,000 words (Chapman et al., 1992). Speech addressed to infants (often called “motherese” or “parentese”) is unique: It has a characteristic prosodic structure with a higher pitch, a slower tempo, and exaggerated intonation contours, and it is syntactically and semantically simplified.

In new studies, we have uncovered another modification parents make when addressing infants—one that may be important to infant learning. We examined natural language input at the phonetic level to infants in the United States, Russia, and Sweden (Kuhl, Andruski, et al., 1997). The study shows that across three very diverse languages, infant-directed speech exhibited a universal alteration of phonetic units when compared to adult-directed speech. Parents addressing their infants produced acoustically more extreme tokens of vowel sounds, resulting in a “stretching” of the acoustic space encompassing the vowel triangle (figure 8.7). A stretched vowel triangle not only makes speech more discriminable for infants, it also highlights critical spectral parameters that allow speech to be produced by the child. The results suggest that at

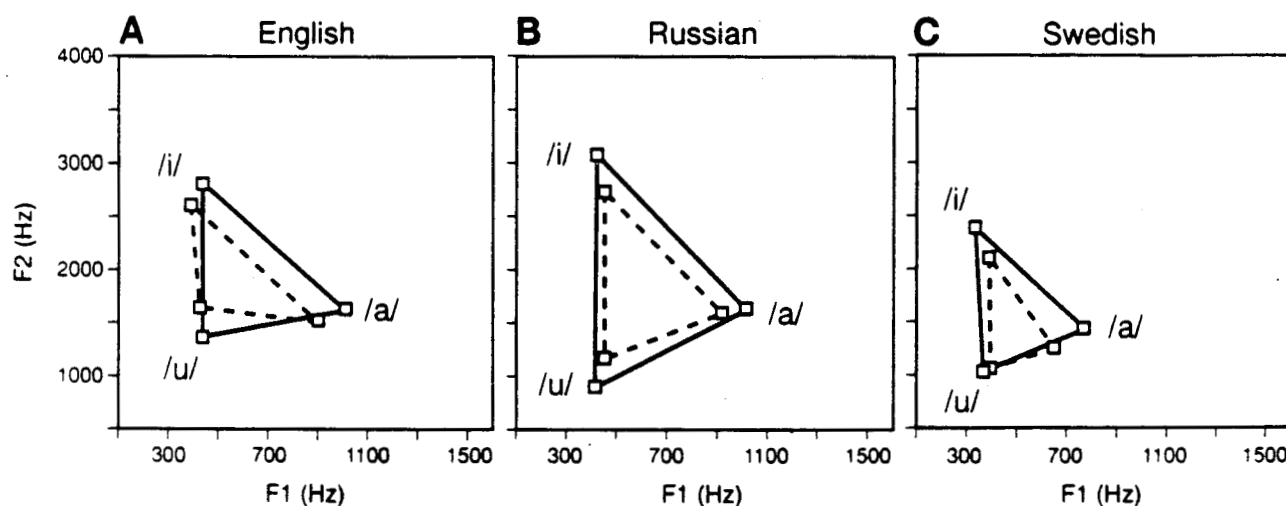

FIGURE 8.7 The vowel triangle of maternal speech directed toward infants (solid line) across three diverse languages shows a “stretching” relative to the adult-directed vowel triangle

(dashed line), an effect that both makes vowels more discriminable and highlights the abstract features that infants must use to produce speech themselves.

the phonetic level of language, linguistic input to infants provides exceptionally well-specified information about the units that form the building blocks for words.

Thus, when adults speak to normally developing infants, they enhance phonetic distinctions. In recent studies, language-delayed children showed substantial improvements in measures of speech and language after treatment in a program in which they listened to speech altered by computer to exaggerate phonetic differences (Merzenich et al., 1996; Tallal et al., 1996). This kind of speech may aid infants' discovery of the dimensions of sound that they need to attend to in order to process speech efficiently. In the study, mothers' vowels in speech to children were what acousticians call "hyperarticulated" (Lindblom, 1990), ones that are perceived by adults as better instances of vowel categories (Iverson and Kuhl, 1995; Johnson, Flemming, and Wright, 1993). Parental speech thus contains more prototypical instances, and as shown in the work reviewed previously, these are the very kinds of sounds that produce the perceptual magnet effect. Language input to infants may therefore provide an ideal signal for constructing perceptual maps.

Brain correlates

Since the classic reports of Broca and Wernicke on patients with language deficits typical of aphasia, we have known that the two hemispheres are not equal in the extent to which they subserve language. In the 1960s, behavioral studies on language processing in normal adults contributed additional evidence of the left-hemisphere specialization for language, showing a dissociation for processing speech (left hemisphere) and nonspeech (right hemisphere) signals (Kimura, 1961).

Studies of the brain's organization of language have appeared in increasing numbers with the advent of modern neuroimaging techniques such as PET, positron emission tomography (Peterson et al., 1990; Posner et al., 1988); fMRI, functional magnetic resonance imaging, (Neville et al., 1998); ERP, event-related potentials (Neville, Mills, and Lawson, 1992; Osterhout and Holcomb, 1992); and MEG, magnetoencephalography (Näätänen et al., 1997). While this field is still emergent, there are some conclusions that take us beyond what early studies have shown regarding language and the brain. The new studies suggest, for example, that there is not one unified "language area" in the brain where linguistic signals are processed. Different brain systems subserve different aspects of language processing, and the language processing areas of the brain include many more regions than the classic Broca's and Wernicke's areas.

The imaging studies confirm a dissociation for processing speech and nonspeech signals found in earlier

behavioral studies. One study (Zatorre et al., 1992) used PET scans to examine phonetic as opposed to pitch processing. Subjects in the study had to judge the final consonant of the syllable in the phonetic task and the pitch of the syllable (high or low) in the pitch task. The results showed that phonetic processing engaged the LH while pitch processing engaged the RH. This dissociation between the phonetic and nonphonetic processing of auditory dimensions is mirrored in studies using vowels at different pitches and MEG (Poeppel et al., 1997).

Given these results, an important question from the standpoint of development is when the left hemisphere becomes dominant in the processing of linguistic information. Lenneberg (1967) hypothesized that the two hemispheres are equipotential for language until approximately two years of age, at which time LH dominance begins to develop and continues until puberty. However, this theory is contradicted by data suggesting that children with LH versus RH damage at an early age displayed different deficits in language abilities: Early LH damage affects language abilities more than early RH damage (Witelson, 1987).

Behavioral studies have established the right-ear advantage (REA) for speech for verbal stimuli and the left-ear advantage (LEA) for musical and environmental sounds using the dichotic listening task in children as young as 2.5 years (Bever, 1971; Kimura, 1963). But what of infants? Glanville, Best, and Levenson (1977) reported an REA for speech contrasts and an LEA for musical sounds using a cardiac orienting procedure in 3-month-olds. Only two studies provide data on infants' differential responses to speech and music at ages younger than 2 months. In one study, infants' discriminative capacities for speech and music were examined in 2-, 3-, and 4-month-old infants using a cardiac-orienting procedure. The results demonstrated an REA for speech discrimination in 3-month and 4-month-old infants, but not in 2-month-old infants. In addition, an LEA was shown for musical-note discrimination at all three ages. Finally, tests on 2-month-olds conducted by Vargha-Khadem and Corballis (1979) showed infants discriminated speech contrasts equally with both hemispheres. In other words, the results suggest that speech may not be lateralized in 2-month-old infants, but becomes so by 4 months of age.

This issue of the onset of laterality and the extent to which it depends on linguistic experience may be resolved with future research using techniques that can be used throughout the life span. One such technique is the mismatched negativity (MMN), a component of the auditorially evoked event-related potential (ERP). The MMN is automatically elicited by a discriminable change in a repetitive sound pattern and its generation

appears to represent the detection of a change in the neural sensory-memory representation established by the repeated stimulus (see Näätänen, 1990, 1992, for review). MMNs to a change in a speech stimulus have been well documented in adult listeners (e.g., Kraus et al., 1992). The MMN has been established in children (Kraus et al., 1993) and most recently in infants (Cheour-Luhtanen et al., 1995; Kuhl, 1998b; Pang et al., 1998). In adult ERP studies, a left-hemisphere asymmetry is evident (Pang et al., 1998), but it has not been observed in newborns (Cheour-Luhtanen et al., 1995).

In summary, there is no strong evidence at present that the bias toward left-hemisphere processing for language is present at birth. The data suggest that it may take experience with linguistically patterned information to produce the left-hemisphere specialization. Thus, there is support for a specialization for language in infancy, but one that develops, rather than one that exists at birth. Moreover, the input that is eventually lateralized to the left hemisphere can be either speech or sign, indicating that it is the linguistic/communicative significance of the signals, rather than their specific form, that accounts for the specialization.

Conclusions

Research has shown that in the first year of life infants learn a great deal about the perceptual characteristics of their native language, and this subsequently alters the perception and production of speech. According to the native language magnet model, perceptual learning early in life results in the formation of stored representations that capture native-language regularities. The theory emphasizes the role of linguistic input. Input does not act like a trigger for innately stored information. Rather, it is mapped in such a way as to “warp” the underlying acoustic space. Stored representations act like perceptual magnets for similar patterns of sound, resulting in maps that specify perceived distances between sounds, and create categories. The map shrinks perceptual distances near a category’s most typical instances and stretches perceptual distances between categories. Perceptual maps differ in adults who speak different languages and are polymodally mapped, containing auditory, visual, and motor information. The magnet effects and the mental maps they produce help explain how native-language speech develops, as well as the relative inability of adults to readily acquire a foreign language.

Introduction

IRA B. BLACK

PLASTICITY, the collective mechanisms that underlie brain mutability and flexibility, enables cognition. Relatively rapid change in brain structure and function generates mind. Characteristic cognitive processes, including perception, learning, and memory, are expressions of brain plasticity. What is the substance of adaptability? In brain and mind that function simultaneously on the molecular, cellular, systems, and cognitive levels, where does plasticity emerge?

The chapters in this section present a unified, emphatic answer. Plasticity is built into the fabric of brain and mind at multiple levels, from the molecular to the cognitive. Indeed, our growing awareness of the continuity and integration of plastic mechanisms across functional levels represents one of the most exciting advances since the last edition of this text. We now can tentatively (though incompletely) trace a number of cognitive functions from experience to gene action, molecular mechanism, system function, and cognitive output.

The emerging unity also suggests that characterization of cognition requires description of plastic mechanisms at multiple levels. The characteristics of specific molecular, cellular, and systems plastic interactions shape the particular cognitive function generated. Conversely, systems and cognitive function regulate underlying molecular and cellular processes. In sum, the form and specific traits of a cognitive function are conferred by multilevel plastic mechanisms.

Analysis, characterization, and classification of plastic functions may provide general insights into the large-scale organization of cognitive architecture. The discovery of common plastic mechanisms underlying apparently disparate cognitive functions may reveal unsuspected commonalities. In contrast, apparently similar cognitive domains may prove to be based on

qualitatively different plastic mechanisms. This knowledge may lead to a taxonomy of cognitive functions currently unavailable.

To illustrate the coherence of plastic mechanisms across multiple domains, this section follows a bottom-up sequence, proceeding from the molecular to the cognitive. Initially, basic molecular and cellular plastic mechanisms associated with learning, memory, and cortical structure are considered. A universal feature of brain and cognitive architecture, the organization of maps, is examined as a prototypical fundamental neurocognitive strategy. Molecular processes underlying map formation are described, and experience-driven plasticity of maps is analyzed. Finally, the perceptual plasticity resulting from map plasticity emphasizes the continuity of plastic mechanisms from the molecular to the cognitive.

Martin, Bartsch, Bailey, and Kandel focus on synaptic plasticity associated with long-term memory. They describe changes in gene action, leading to messenger RNA and protein synthesis that alter long-term synaptic function. A number of plastic molecular mechanisms that contribute to long-lasting forms of synaptic plasticity are defined.

Lynch uses the model of long-term potentiation (LTP) to explore the phenomenon of memory consolidation. During the process of consolidation, newly encoded information gradually becomes resistant to disruption. He presents evidence that consolidation is dependent on the action of synaptic cell adhesion molecules, specifically integrin receptors, that alter synaptic function. Lynch hypothesizes that specific patterns of synaptic transmission activate latent integrin receptors that stabilize LTP and memory function over time, constituting consolidation. The therapeutic implications of these insights are discussed.

Levine and Black describe recently discovered novel mechanisms governing hippocampal synaptic plasticity, trophic regulation of synaptic strength. Specific neurotrophins, which are critical for long-term neuronal development, also regulate synaptic function acutely. A neurotrophin known as brain-derived neurotrophic factor (BDNF) increases responsiveness of postsynaptic hippocampal neurons to glutamatergic stimulation by enhancing the responsiveness of NMDA receptors. The relationships among depolarization, gene expression, trophic actions, and transmitter function in synaptic plasticity are explored in detail.

Whereas the previously mentioned chapters focus on molecular and cellular plastic mechanisms localized to the synapse, McEwen reviews hippocampal plasticity elicited by circulating adrenocortical, gonadal, and thyroid hormones. For example, the formation and destruction of synapses during the estrous cycle and the effects

of glucocorticoids on declarative and contextual memory are described. In sum, hippocampal plasticity is placed in the larger context of somatic physiology, allowing experience to access cognitive processes through the endocrine system.

The broad issue of permissive versus instructive stimulus regulation of the development of functional cortical architecture is examined by Katz, Weliky, and Crowley. Using the visual system as a model, the interaction of spontaneous correlated electrical activity and innate information in the genesis of ocular dominance and orientation columns is explored. Employing new approaches, they conclude that elaboration of cortical circuits requires patterned activity in a permissive rather than instructive sense, and that additional intrinsic signals may guide the formation of functional cortical architecture.

The mechanisms generating map formation, a central feature of brain and cognitive architecture, are described by Zhou and Black. Multiple molecular cues guide axons in a topographically precise fashion, resulting in the formation of sequences of maps. The cues are attractive or repulsive and diffusible or membrane bound. Among multiple guidance molecules, two groups play central roles: the tyrosine kinase receptors and ligands, and cell adhesion molecules. The former include the attractive neurotrophins and the repulsive Eph family of ligands and receptors. Gradients of membrane-bound Eph receptors and ligands on innervating and target fields confer specificity, and cell adhesion molecules stabilize the connections.

Maps are characterized by striking plasticity. Altered cognitive experience, including changes in sensory input and learning, elicit marked changes in map structure and function, described by Kaas. Map plasticity occurs in cortex and in subcortical structures, including the thalamus and brain stem, and involves the somatosensory, visual, auditory, and motor systems. Some alterations are virtually instantaneous, whereas others evolve over months. Map plasticity may result in misperception or in improvement of sensorimotor skill with practice, for example. Thus experience regulates map plasticity, which, in turn, evokes cognitive plasticity. It is currently not known whether underlying molecular mechanisms include those described by Zhou and Black. Map plasticity represents one set of processes in which cognitive function regulates molecular plastic mechanisms governing brain architectural plasticity.

Recanzone presents evidence that reorganization of cortical representations improves perceptions and the acquisition of a variety of skills throughout life. Cortical plasticity is central to cognition.

To epitomize, this section provides examples of plastic mechanisms—from the molecular, cellular, and systems to the cognitive—that interact to generate mind.

9 Molecular Mechanisms Underlying Learning-Related Long-Lasting Synaptic Plasticity

KELSEY C. MARTIN, DUSAN BARTSCH, CRAIG H. BAILEY, AND ERIC R. KANDEL

ABSTRACT Learning is the process whereby we acquire information about the world, and memory is the process whereby we retain that information. Memory can be divided into at least two temporally distinct components: short-term memory that lasts for minutes to hours and long-term memory that lasts for days, weeks, or even years. Over the past several decades, molecular and cell biological studies of learning and memory have indicated that these behavioral processes are reflected at the cellular level by changes in synaptic plasticity—the ability of neurons to modulate the strength and structure of their synaptic connections with experience (Bliss and Collingridge, 1993; Martin and Kandel, 1996). Thus, in the simplest terms, what these studies have shown is that memories are stored as increases in the strength and, at least in some cases, the number or pattern of synapses in the brain. Like memory, learning-related synaptic plasticity can exist in at least two different forms. First, there is a short-term form that has been found to depend on the covalent modification of already synthesized molecules, leading to an alteration in the strength of preexisting connections. Second, there is a long-term form that has been shown to depend on the synthesis of new messenger RNAs and new proteins, leading to the growth of new synaptic connections. Here we consider the storage of long-term memory by examining the changes in gene expression in the nucleus, the changes in the structure and function of the synapse, and the communication between the synapse and the nucleus that underlie the induction and stabilization of long-lasting forms of synaptic plasticity.

The gill-withdrawal reflex in Aplysia as a model system for studies of learning-related synaptic plasticity

We will focus on studies of learning, memory, and synaptic plasticity in the central nervous system of a higher

invertebrate, the marine mollusc *Aplysia*. *Aplysia* has proven advantageous for cellular studies of memory for a variety of reasons. First, the animal can undergo simple forms of learning. Second, it has a tractable nervous system, consisting of approximately 20,000 neurons, many of which are large, invariant, and readily identifiable. As a result, the neural circuitry underlying many of its behaviors has been partially characterized. One such behavior involves the reflex in which the animal withdraws its gill in response to tactile stimulus of the gill. This gill-withdrawal reflex is mediated to a large extent by mechanoreceptor sensory neurons from the siphon that make synaptic contact with motor neurons from the gill. As with defensive behaviors in other species, the gill-withdrawal reflex can undergo several types of behavioral modification, including both nonassociative forms such as habituation and sensitization, and associative forms such as classical conditioning.

Like other forms of learning, habituation and sensitization can exist in both short-term and long-term forms. A single tail shock produces short-term sensitization of the gill-withdrawal reflex that lasts for minutes. Repeated tail shocks given at spaced intervals produce long-term sensitization of the gill-withdrawal reflex that lasts for days or even weeks (Frost et al., 1985).

Of particular value for studies of the cellular and molecular mechanisms underlying sensitization, the critical components of the neuronal circuitry that mediates the gill-withdrawal reflex can be reconstituted in cell culture, where a single presynaptic sensory neuron makes synaptic contact with a single postsynaptic motor neuron. These synaptic connections in culture are stable and exhibit both short- and long-lasting forms of synaptic plasticity. This plasticity can be modified by application of serotonin (5-HT), the modulatory neurotransmitter released by facilitatory interneurons in the intact animal. A single application of 5-HT to the culture dish produces *short-term* facilitation: an increase in the magnitude of the excitatory postsynaptic potential (EPSP) formed between

ERIC R. KANDEL Howard Hughes Medical Institute and Center for Neurobiology and Behavior, College of Physicians and Surgeons of Columbia University, New York, N.Y.

the sensory and motor neuron that lasts for minutes and that does not depend on new protein synthesis.

In contrast, five repeated applications of serotonin given at timed intervals produce long-term facilitation: an increase in the strength of the EPSP that persists for at least 24 hours that requires new RNA and protein synthesis and involves the growth of new synaptic connections between the sensory and motor neurons. To test the role of specific molecules in both short- and long-term facilitation, and in the conversion of the short-term form to one of longer duration, the large *Aplysia* nerve cells can be microinjected with a variety of compounds. As a result, the *Aplysia* sensory-to-motor neuron culture system provides an experimentally accessible model system for analysis of the cellular and molecular mechanisms underlying learning-related synaptic plasticity.

In the past several years, studies of learning and memory in other species have converged to indicate the generality of many cellular and molecular mechanisms used during long-term sensitization in *Aplysia*. Two particularly well-developed systems for the analysis of learning and memory include olfactory learning in *Drosophila* (Davis, 1996) and hippocampal-mediated long-term potentiation (LTP) in rodents (Bliss and Collingridge, 1993). These studies show that similar mechanisms of learning and memory formation are used in species as diverse as *Aplysia*, *Drosophila*, and rodents, and that similar cellular mechanisms underlie a variety of forms of memory, including the implicit or nondeclarative acquisition of motor skills and other tasks, and the explicit, hippocampus-based acquisition of knowledge about people, places, and things (Squire, 1992).

Long-term memory requires changes in gene expression

Neither short-term behavioral sensitization in the animal nor short-term facilitation in dissociated cell culture requires ongoing macromolecular synthesis (Montarolo et al., 1986; Schwartz, Castellucci, and Kandel, 1971). Long-lasting synaptic plasticity differs from short-term in requiring translation and transcription. Inhibitors of RNA and protein synthesis selectively block the induction of the long-term changes in both the semi-intact preparation (Castellucci et al., 1989) and in primary cell culture (Montarolo et al., 1986). Importantly, the induction of long-term facilitation at this single synapse exhibits a critical time window in its requirement for protein and RNA synthesis characteristic of that necessary for learning in both vertebrate and invertebrate animals (Agranoff, 1972; Barondes, 1975; Davis and Squire, 1984; Flexner, Flexner, and Stellar, 1965; Montarolo et

al., 1986). This fact indicates that there is a critical consolidation period during which new genes must be expressed in order to convert transient changes in synaptic strength to more enduring modifications.

PROTEIN KINASE A IS CRITICAL FOR THE TRANSMISSION OF SIGNALS FROM THE SYNAPSE TO THE NUCLEUS Serotonin released by interneurons in vivo or applied directly to sensorimotor cocultures binds to 5-HT receptors on the sensory neuron membrane and activates adenylyl cyclase. The resulting increase in cAMP, in turn, activates the cAMP-dependent protein kinase (PKA). PKA plays a critical role in both short- and long-term facilitation. Indeed, cAMP analogues can evoke both short- and long-term facilitation, and inhibitors of PKA block both forms of facilitation (Ghirardi et al., 1992; Montarolo et al., 1986). How PKA participates in the RNA and protein synthesis-dependent process was illustrated by an experiment carried out by Bacskaï and associates (1993). They monitored the subcellular localization of the free PKA catalytic subunit and found that with one pulse of serotonin, which produces short-term facilitation, the catalytic subunit was restricted to the cytoplasm. With repeated pulses of serotonin, which induce long-term facilitation, the catalytic subunit translocated to the nucleus, where it presumably phosphorylates transcription factors and thereby regulates gene expression. Both cAMP and PKA are essential components of the signal-transduction pathway for consolidating memories not only in *Aplysia* but also for certain types of memory in *Drosophila* and mammals. Several olfactory learning mutants in *Drosophila* map to the cAMP pathway (R. L. Davis, 1996; R. L. Davis et al., 1995; Drain, Folkers, and Quinn, 1991) indicating that blocking PKA function blocks memory formation in flies. In parallel, the late but not the early phase of LTP of the CA3 to CA1 synapse in the hippocampus is impaired by pharmacological or genetic interference of PKA (Abel et al., 1997; Frey, Huang, and Kandel, 1993; Huang, Lin, and Kandel, 1994). This interference with PKA blocks long-lasting spatial memory in mice without interfering with short-term memory.

CREB: THE GENETIC SWITCH FOR THE CONSOLIDATION OF LONG-TERM MEMORY Increases of cAMP concentration induce gene expression by activating transcription factors that bind to the cAMP-responsive element (CRE) (Montminy et al., 1986). The CRE-binding protein CREB (Hoeffer et al., 1988) is a major target of PKA phosphorylation of a regulatory P-box, which in turn activates transcription by binding to the CRE-binding protein CBP and basal transcription machinery (Gonzalez and Montminy, 1989). During long-term facilitation in *Aplysia* neurons, PKA appears to activate gene

expression via an *Aplysia* CREB (Dash, Hochner, and Kandel, 1990; Bartsch et al., 1998). Dash, Hochner, and Kandel first tested the role of CREB in long-term facilitation by microinjecting CRE oligonucleotides into sensory neurons. The CRE oligonucleotide binds to the CREB protein within the cell and thereby prevents it from binding to CRE sites in the regulatory regions of cAMP-responsive genes. While injection of the CRE oligonucleotide had no effect on short-term facilitation, it selectively blocked long-term facilitation (figure 9.1A, B). Kaang, Kandel, and Grant (1993) further explored the mechanisms of CREB activation in long-term facilitation by microinjecting two constructs into *Aplysia* sensory neurons: an expression plasmid containing a chimeric transacting factor made by fusing the GAL4 DNA-binding domain to the mammalian CREB-activation domain and a reporter plasmid containing the chloramphenicol acetyltransferase (CAT) gene under the control of GAL4 binding sites (figure 9.1C, D). The chimeric transcription factor binds to UASg GAL4-binding sites, but only activates transcription when the CREB P-box is phosphorylated. Since the yeast GAL4-binding site is not regulated by *Aplysia* transcription factors, the transcription of the CAT reporter gene is induced only when the activation domain of the GAL4-CREB hybrid protein is phosphorylated. Following coinjection of these two plasmids into sensory neurons, exposure to 5-HT produced a tenfold stimulation of CAT expression (Kaang, Kandel, and Grant, 1993). Finally, Bartsch and associates (1998) directly demonstrated that CREB is essential for long-term facilitation. They cloned the *Aplysia* CREB gene and showed that blocking expression of one of the CREB1 gene products of the CREB1a protein in sensory neurons by microinjection of antisense oligonucleotides or antibodies blocks long-term but not short-term facilitation. Not only is CREB1a activator necessary for long-term facilitation, but it is also sufficient to induce long-term facilitation. Thus, sensory cell injection of recombinant CREB1a phosphorylated in vitro by PKA led to an increase in EPSP amplitude at 24 hours in the absence of any serotonin stimulation.

In mammals and *Drosophila*, CREB messenger RNAs (mRNAs) undergo extensive splicing: At least six different isoforms of CREB have been cloned in both mammals and *Drosophila* (Ruppert et al., 1992; Yin, Wallach, et al., 1995). To determine the role of specific CREB isoforms in the cells that participate in memory storage, Bartsch and colleagues (1998) characterized the CREB isoforms that are expressed in *Aplysia* sensory neurons and established their particular role in long-term facilitation. In addition to the CREB1 α mRNA, which encodes the CREB1a activator, they detected a second CREB1 β mRNA encoding the additional CREB1 forms CREB1b

and CREB1c. CREB1b encodes a CRE-binding leucine zipper transcriptional repressor that forms heterodimers with CREB1a and blocks activation from the CRE. Thus microinjection of CREB1b into sensory neurons blocks selectively long-term facilitation induced by 5 pulses of serotonin. CREB1c protein is a cytoplasmic modulator of both short- and long-term facilitation: microinjection of CREB1c into sensory cells increases both short-term and long-term facilitation when paired with only one pulse of serotonin. Since unphosphorylated CREB1c inhibits calcium/calmodulin-dependent kinase (CaMK) activity in *Aplysia* neuronal extracts, one possibility is that CREB1c produces its actions by removing inhibitory constraints mediated by calmodulin or CaMKII. Together, these results indicate that in the sensory neuron, a critical site for memory storage, CREB isoforms act together in a coordinated regulatory unit that can switch a covalent-mediated short-term facilitation to a transcriptionally dependent long-term form.

The transcriptional switch in long-term facilitation is not composed of only the CREB1 regulatory unit. Bartsch and associates (1995) have shown that another member of the CREB gene family, ApCREB2, a CRE-binding transcription factor constitutively expressed in sensory neurons, is a critical component of the genetic switch that converts short- to long-term facilitation. ApCREB2 resembles human CREB2 and mouse ATF4 (Hai et al., 1989; Karpinski et al., 1992), and like CREB1 β , ApCREB2 functions as a repressor of long-term facilitation. Thus, injection of anti-ApCREB2 antibodies into *Aplysia* sensory neurons causes a single pulse of serotonin, which normally induces only short-term facilitation lasting minutes. To evoke facilitation that lasts more than 1 day requires both transcription and translation, and is accompanied by a growth of new synaptic connections (figure 9.2).

These studies reveal that long-term synaptic changes are governed by both positive and negative regulators, and that the transition from short-term facilitation to long-term facilitation thus requires the simultaneous removal of transcriptional repressors and activation of transcriptional activators. These transcriptional repressors and activators can interact with each other both physically and functionally. It is likely that the transition is a complex process involving temporally distinct phases of gene activation, repression, and regulation of signal transduction. Differences in the kinetics whereby activators are stimulated and repressors relieved could define the optimal time window separating training trials and account for the well-established difference between massed and spaced training (Carew, Pinsker, and Kandel, 1972; Pinsker et al., 1973; Tully et al., 1994; Yin et al., 1994; Yin, Del Vecchio, et al., 1995).

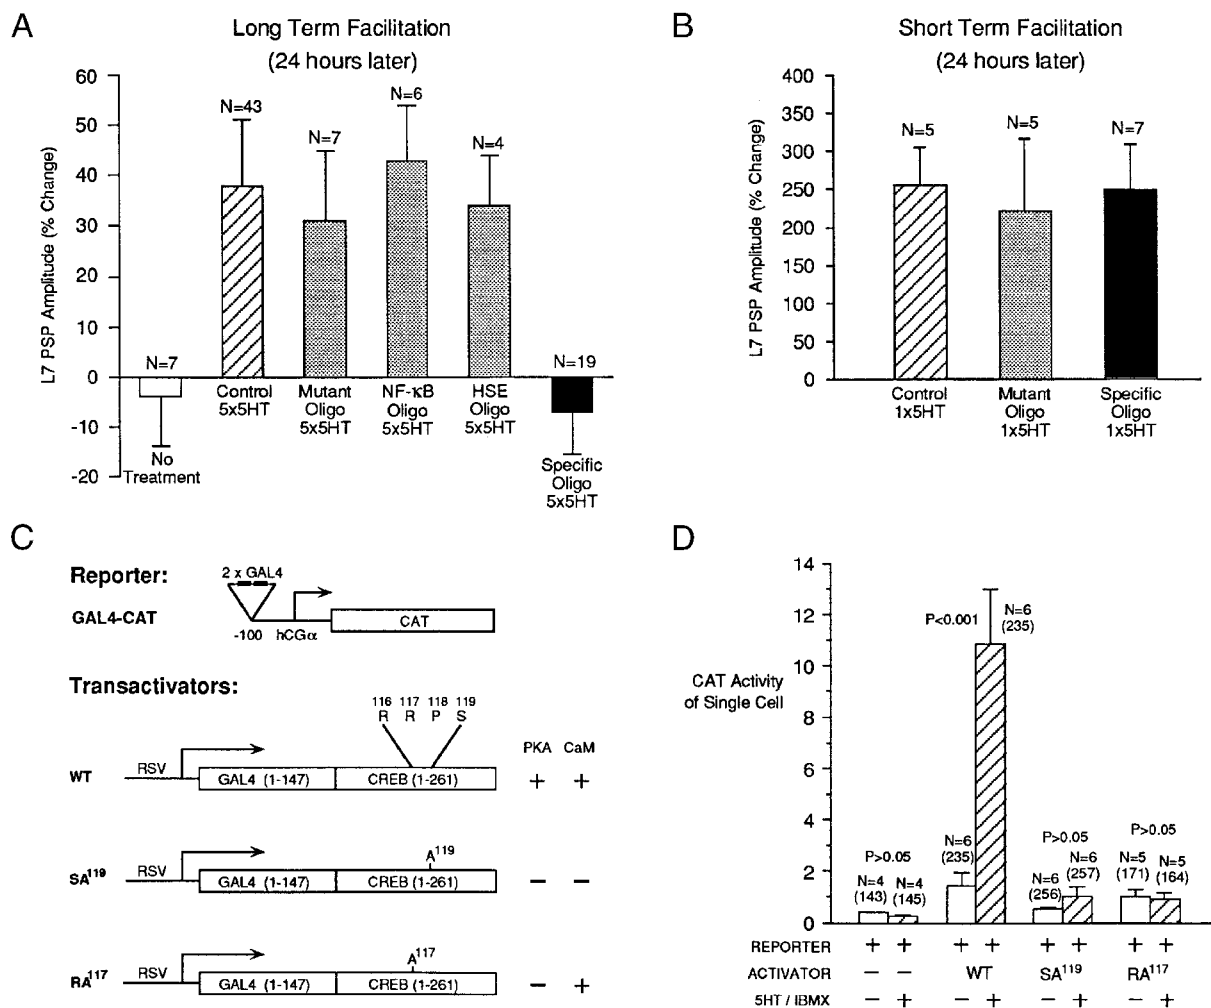

FIGURE 9.1 (A, B) Injection of CRE oligonucleotides blocks 5-HT-induced long-term facilitation. (A) Summary of the blockade of the 5-HT-induced increase in EPSP amplitude by CRE injection. The height of each bar is the percentage change in the EPSP amplitude \pm SEM retested 24 hr after treatment. (A two-tailed *t*-test comparison of means indicated that the decrease in EPSP in cultures injected with CRE oligonucleotide is significantly different [$p < .05$] from the increase in the EPSP in the cells injected with either the mutant or NF- κ B oligonucleotides.) (B) Summary of the pooled data for short-term facilitation 24 hours after injection. In contrast to long-term facilitation, the 5-HT (5 μ M) was applied after the EPSP was first depressed. Five stimuli were given with an interstimulus interval of 30 seconds, resulting in 70–80 percent depression in EPSP amplitude. Application of 5-HT after the fifth stimulus produced an increase in EPSP amplitude by the seventh stimulus. The increase in short-term facilitation was measured by calculating the percentage increase in the seventh EPSP amplitude as compared with the fifth EPSP amplitude. Because the facilitation here was of a depressed EPSP, the percentage facilitation is larger than the long-term, where only the nondepressed EPSP was examined. (From Dash, Hoehner, and Kandel, 1990.) (C, D) 5-HT/IBMX leads to activation of CREB through the phosphorylation of PKA. (C) DNA constructs used for transactivation experiments. DNA-binding domain of yeast GAL4 transcription factor (amino acids 1–147)

fused to wild-type or mutated forms of mammalian CREB transactivation domains (amino acids 1–261). Wild-type and mutated phosphorylation consensus sequences are indicated in single-letter amino acid code above constructs. The wild-type sequence (RRPS) is a phosphorylation substrate for both protein kinase A (PKA) and calcium/calmodulin-dependent kinase (CaM) at Ser¹¹⁹. SA¹¹⁹ contains a substitution of Ser¹¹⁹ with Ala¹¹⁹, preventing phosphorylation by either kinase. RA¹¹⁷ contains a substitution of Arg¹¹⁷ with Ala¹¹⁷, abolishing the PKA site, but leaving intact the CaMK consensus phosphorylation sequence. GAL4-CREB fusion proteins were constitutively expressed in pNEX δ vector and injected with the reporter construct (GAL4-CAT) containing two copies of the GAL4 site upstream of human chorionic gonadotropin α -subunit gene driving the CAT gene. (D) Quantitative analysis of 5-HT-regulated CREB transactivation. The wild-type (WT) GAL4-CREB transactivator enhances 5-HT/IBMX-mediated expression of CAT, whereas mutant (SA¹¹⁹ and RA¹¹⁷) GAL4-CREB show no enhancement. Pairs of sensory clusters were injected and treated in parallel; each lane represents CAT activity of one sensory cluster. CAT activity is expressed as the percentage of substrate acetylated ($\times 103$); histograms show pooled area, *N* = number of animals, and value in parentheses is number of injected neurons. Mean, SEM, and *p* value from two-tailed paired test are shown. (From Kaang, Kandel, and Grant, 1993.)

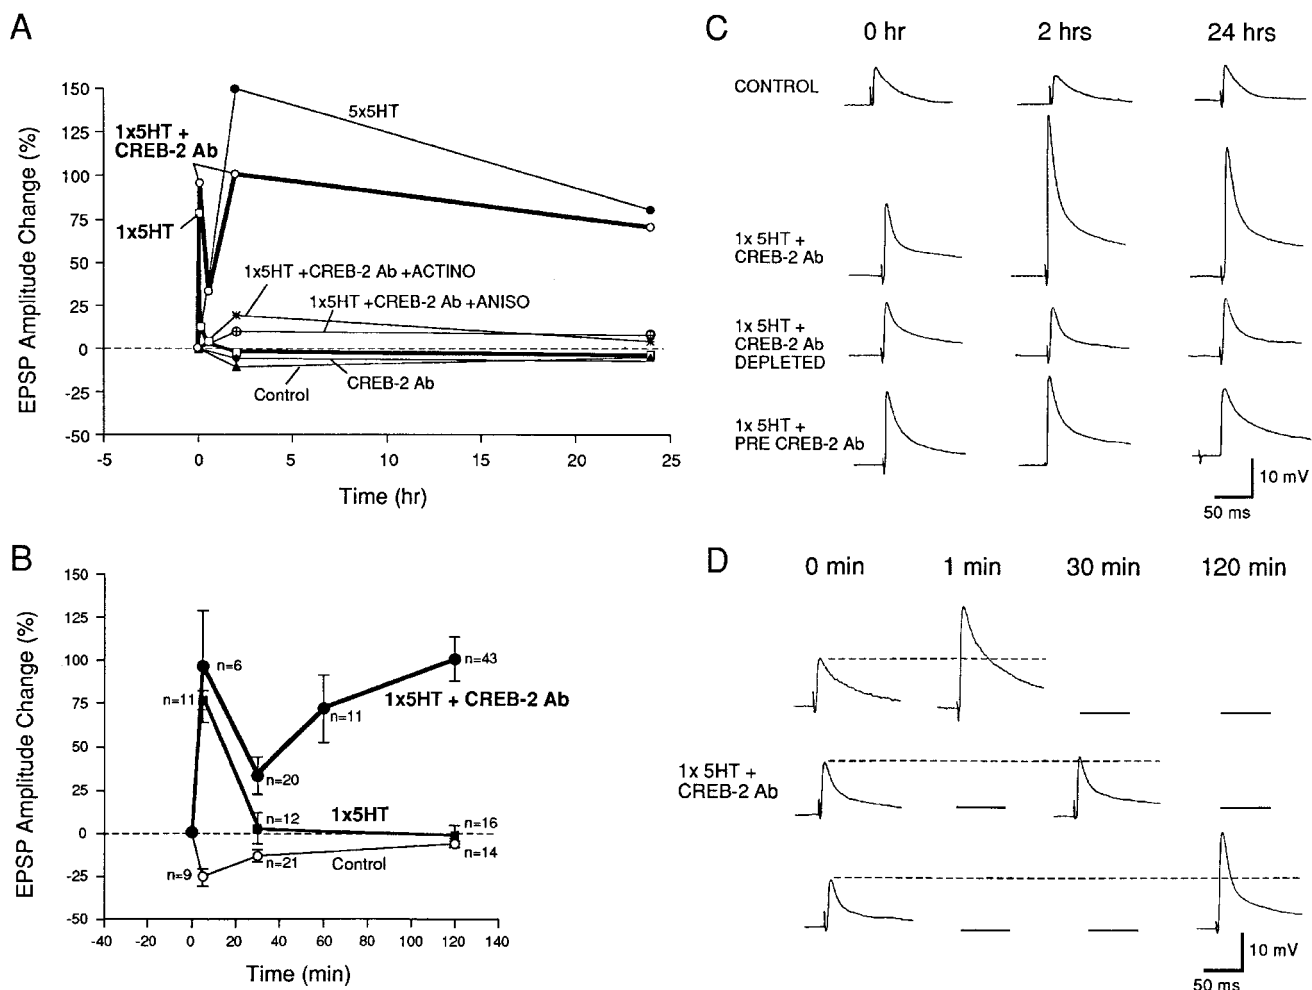

FIGURE 9.2 Time course of the effects of injection of ApCREB2 antiserum on short- and long-term facilitation. (A) Time course of excitatory postsynaptic potential (EPSP) amplitude changes recorded in motor neuron L7 in response to stimulation of the sensory neuron (expressed as percent change in the amplitude of the EPSP) after single and multiple applications of 5-HT to *Aplysia* sensorimotor neuron cocultures. Changes in EPSP amplitude after application of one 5-min pulse of 5-HT (1 × 5-HT, short-term facilitation) and one 5-min pulse of 5-HT paired with injection of anti-ApCREB2 antibodies (1 × 5-HT + CREB-2 Ab, both in boldface lines) are compared with changes in EPSP amplitude induced by five pulses of 5-HT (5 × 5-HT) at 2 and 24 hr. While the EPSP facilitation decays rapidly after one pulse of 5-HT (with a return to base line after 10 min), pairing one pulse with 5-HT with injection of anti-ApCREB2 antibodies induces a long-term facilitation paralleling that of 5 × 5-HT. This long-term facilitation is abolished by the application of the protein synthesis inhibitor anisomycin (1 × 5-HT + CREB-2 Ab + ANISO) or the RNA synthesis inhibitor actinomycin D (1 × 5-HT + CREB-2 Ab + ACTINO) during the

training. The difference in EPSP amplitude at 2 hr between 5 × 5-HT and 1 × 5-HT + CREB-2 Ab may reflect the transient protein synthesis-dependent, but RNA synthesis-independent, component of long-term facilitation 2 hr after 5-HT stimulation (29). The controls are either untreated (control) or injected with ApCREB2 antiserum without 5-HT administration (CREB-2 Ab). (B) Comparison of the time course of the EPSP amplitude changes in the first 2 hr after application of a single 5-min pulse of 5-HT with or without injection of CREB-2 antibody. The control cells were not exposed to 5-HT. (C) Example of EPSPs recorded in motoneuron L7 after stimulation of the sensory neuron before (0 hr) and 2 and 24 hr after 5-HT treatment. One pulse of 5-HT paired with the injection of an ApCREB2 antiserum induces a significant increase in EPSP amplitude at 2 and 24 hr, but injection of the preimmune serum (PRE-CREB-2 Ab) or depleted immune serum does not induce long-term facilitation. (D) Examples of EPSPs recorded at indicated times in cocultures injected with ApCREB2 antiserum paired with one 5-min pulse of 5-HT. (Reproduced with permission from Bartsch et al., copyright 1995, Cell Press.)

The balance between CREB activator and repressor isoforms is also critically important in long-term behavioral memory, as first shown in *Drosophila*. Expression of an in-

hibitory form of CREB (dCREB-2b) blocks long-term olfactory memory but does not alter short-term memory (Yin et al., 1994). Overexpression of an activator form of

CREB (dCREB-2a) increases the efficacy of massed training in long-term memory formation (Yin, Del Vecchio, et al., 1995).

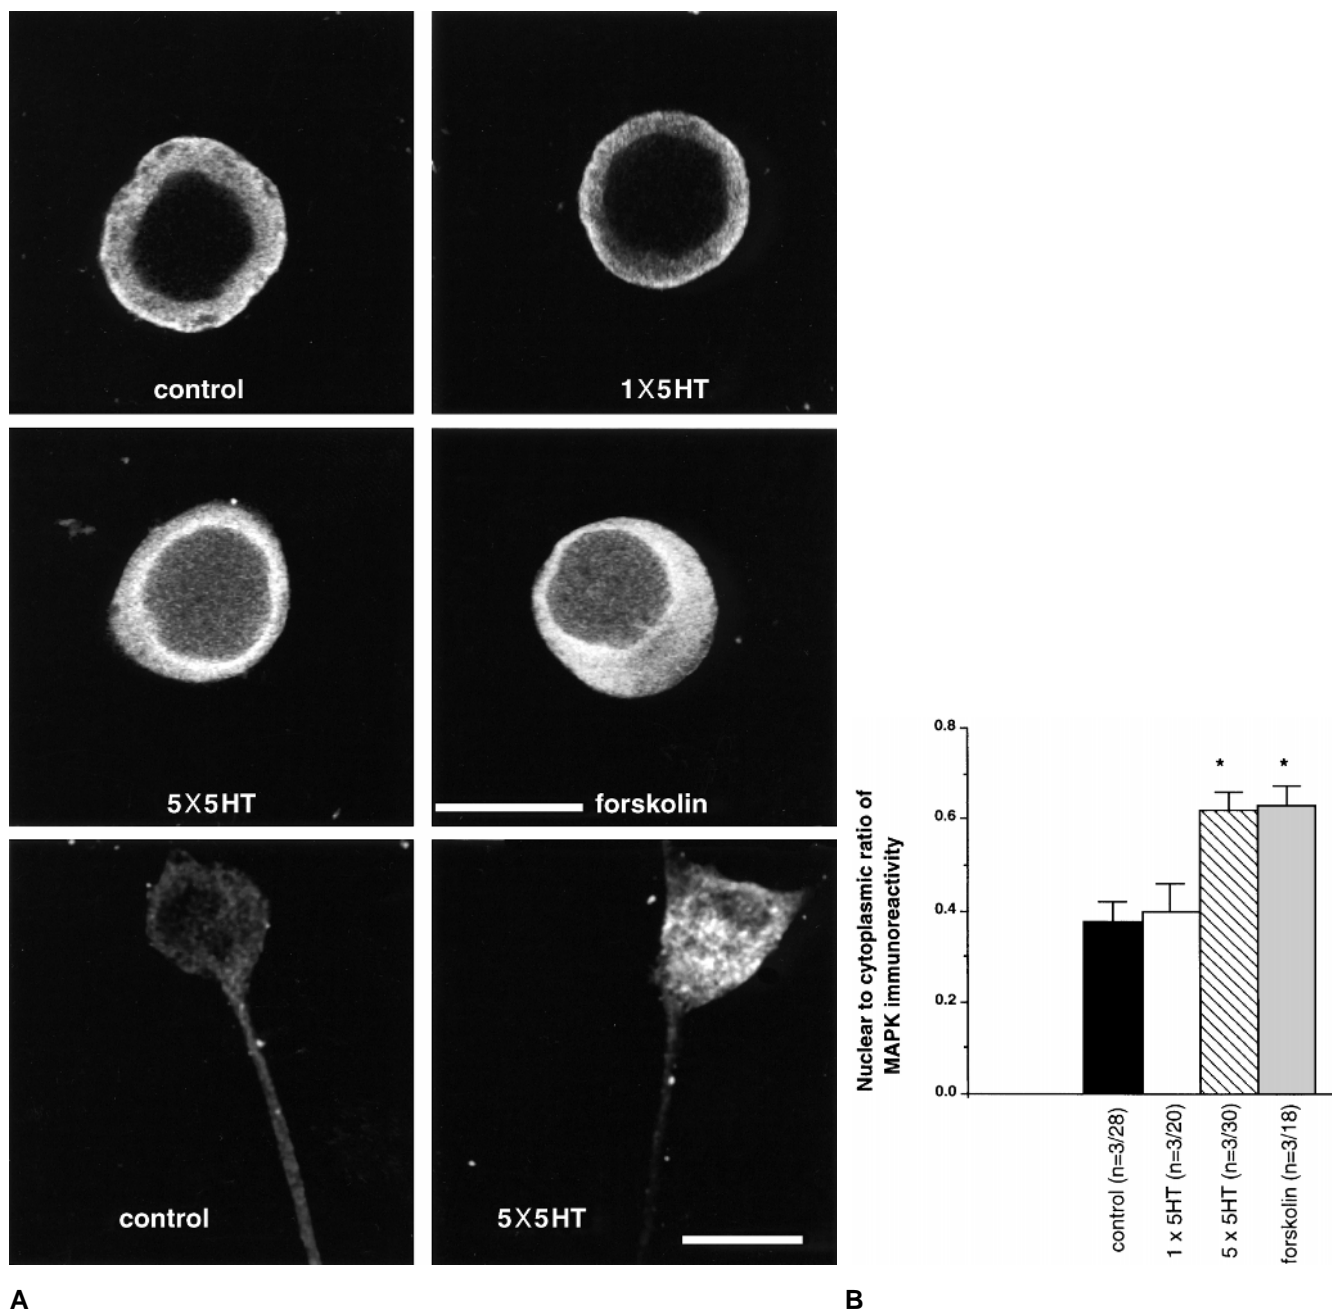

The CREB-mediated response to extracellular stimuli can be modulated by a number of kinases (PKA, CaMKII, CaMKIV, RSK2, MAPK, and PKC) and phosphatases (PP1 and calcineurin). The CREB regulatory unit may therefore serve to integrate signals from various signal transduction pathways. This ability to integrate signaling as well as mediate activation or repression may explain why CREB is so central to memory storage (Martin and Kandel, 1996).

MAPK ALSO CARRIES SIGNALS FROM THE SYNAPSE TO THE NUCLEUS As discussed earlier, the transcriptional switch for the conversion of short- to long-term memory requires not only the activation of CREB1 but also the removal of the repressive action of CREB2, which lacks consensus sites for PKA phosphorylation (Bartsch et al., 1995). It does, however, have two conserved sites for MAPK phosphorylation. A number of features make MAPK an attractive candidate for playing a role in long-term facilitation. First, the MAPK system mediates graded responses to extracellular signals (Marshall, 1995). For example, in PC12 cells, EGF causes transient activation of MAPK that results in cell proliferation, while NGF causes sustained activation of MAPK, which leads to its nuclear translocation and results in neuronal differentiation. This gradation of response may be a molecular parallel to the gradation of synaptic strengthening in response to environmental stimuli, important for learning in both vertebrates and invertebrates. Similar to the PKA translocation, translocation of MAPK to the nucleus provides an attractive potential mechanism for the transition between the covalent short-term forms and transcription-dependent long-term forms of memory. Furthermore, the MAPK pathway interacts with the cAMP pathway in PC12 cells and in neurons, indicating that MAPK might participate with PKA in the consolidation of long-term memory.

To test this possibility, Martin, Michael, and colleagues (1997) and Michael and Martin (1998) examined the subcellular localization of an *Aplysia* ERK2 homologue in sensorimotor neuron cocultures during short- and long-term facilitation. Whereas MAPK immunoreactivity was predominantly localized to the cytoplasm in both sensory and motor neurons during short-term facilitation, MAPK translocated into the nucleus of the presynaptic sensory but not the postsynaptic motor cell during serotonin-induced long-term facilitation (figure 9.3). Presynaptic but not postsynaptic nuclear translocation of MAPK was also triggered by elevations in intracellular cAMP, indicating that the cAMP pathway

activates the MAPK pathway in a neuron-specific manner. Injection of anti-MAPK antibodies or of MAPK kinase inhibitors (PD98059) into the presynaptic sensory cell selectively blocked long-term facilitation without affecting short-term facilitation. Thus, MAPK appears to be necessary for the long-term form of facilitation. The involvement of MAPK in long-term plasticity may be quite general: Martin, Michael, and associates (1997) and Impey and colleagues (1998) found that cAMP also activated MAPK in mouse hippocampal neurons, suggesting that MAPK may play a role in hippocampal long-term potentiation. The requirement for MAPK during hippocampal LTP has been shown by English and Sweatt, (1996, 1997), who demonstrated that ERK1 is activated in CA1 pyramidal cells during LTP and that bath application of MAPK kinase inhibitors blocks LTP.

THE INDUCTION OF IMMEDIATE EARLY GENES The activation of adenylyl cyclase, the increase in cAMP concentration with the resulting dissociation of the catalytic subunit of PKA and its translocation to the nucleus, and the phosphorylation of CREB are all unaffected by inhibitors of protein synthesis. Where then does the protein synthesis-dependent step that characterizes the consolidation phase appear? Clearly, it must require an additional step—the activation of genes by CREB. To follow further the sequence of steps whereby CREB leads to the stable, self-perpetuating long-term process, Alberini and colleagues (1994) characterized the immediate early genes induced by cAMP and CREB. In a search for possible cAMP-dependent regulatory genes that might be interposed between constitutively expressed transcription factors and stable effector genes, Alberini and colleagues (1994) focused on the CCAAT enhancer-binding protein (C/EBP) transcription factors. They cloned an *Aplysia* C/EBP homologue (ApC/EBP) and found that its expression was induced by exposure to serotonin. Induction of ApC/EBP mRNA is rapid and transient, and occurs in the presence of protein synthesis inhibitors, characteristic of immediate early gene. To determine whether ApC/EBP is necessary for the induction and maintenance of long-term facilitation, Alberini and colleagues (1994) used three different approaches: First, they interfered with the binding of the ApC/EBP to its DNA-binding element (ERE) by injecting oligonucleotides that compete for the binding activity of the endogenous ApC/EBP to its target sequence. Second, they blocked the synthesis of endogenous ApC/EBP by injecting ApC/EBP antisense RNA into the sensory cells. Third, they blocked ApC/EBP by injecting an anti-ApC/EBP antiserum into the sensory neurons. All these blocked long-term facilitation but had no effect on short-term facilitation

A

FIGURE 9.3 MAPK translocates into the nucleus of isolated sensory neurons in culture. Five-day-old cultures of isolated cells were mock treated (control), or treated with one pulse of serotonin ($1 \times 5\text{-HT}$), five pulses of serotonin ($5 \times 5\text{-HT}$), or $50 \mu\text{m}$ forskolin in 0.1% DMSO for 30 min. Optical sections were taken through the cell bodies by confocal microscopy, and the mean fluorescence in the nucleus and cytoplasm was determined. (A) In the top four images, examples of optical sections taken through the cell bodies of sensory neurons mock treated (control), treated with one pulse of serotonin ($1 \times 5\text{-HT}$), with five pulses of serotonin ($5 \times 5\text{-HT}$), or with forskolin. Scale bar = $50 \mu\text{m}$. The bottom two images are single optical sections taken through the initial axon segment and cell

B

soma of sensory cells mock treated (control) or treated with five pulses of serotonin ($5 \times 5\text{-HT}$), illustrating the apparent translocation of MAPK from the process to the soma. Scale bar = $50 \mu\text{m}$. (B) Histogram of the mean nuclear-to-cytoplasmic ratio of MAPK immunoreactivity in sensory neurons in mock-treated cultures (control), cultures treated with one pulse of serotonin ($1 \times 5\text{-HT}$), five pulses of serotonin ($5 \times 5\text{-HT}$), or forskolin. Error bars represent SE. Asterisk, $p < .01$ compared to control and one pulse of serotonin. The n represents the number of individual culture dishes/total number of individual cells. Averages were obtained from each culture dish, and these were then averaged to obtain the mean presented in the histogram. (From Martin, Michael, et al., 1997.)

FIGURE 9.4 Induction of ApC/EBP mRNA. (A) ApC/EBP mRNA expression in CNS of untreated *Aplysia*, of *Aplysia* treated in vivo with the indicated drugs for 2 hr at 18°C, or dissected without treatment and kept at 18°C in culture medium. Four independent experiments are shown, in which 10 µg of total RNA extracted from CNSs of untreated (-) or treated *Aplysia*, as indicated, were electrophoresed, blotted, and hybridized with ³²P-labeled ApC/EBP (top) or S4 (bottom) probes. The latter encodes the *Aplysia* homologue of S4 riboso-

mal protein,⁵⁹ which is constitutively expressed and used as a loading control. Zero indicates RNA extracted immediately after dissection of *Aplysia* CNS. Two-hour dissection represents RNA extracted from *Aplysia* CNS dissected and incubated in culture medium for 2 hr at 18°C. (B) Time course of ApC/EBP mRNA induction following 5-HT treatment. Times of treatment are indicated. Five µg of total RNA extracted from total CNS of in vivo treated *Aplysia* were analyzed as described in B. (From Alberini et al., 1994.)

(figure 9.4). Thus the induction of ApC/EBP seems to serve as an intermediate component of a molecular switch activated during the consolidation period.

The existence of C/EBP, a cAMP-regulated immediate early gene that is itself a transcription factor and regulates other genes, leads to a model of sequential gene activation. CREB1a, CREB1b, CREB1c, and CREB2 represent the first level of control, since all are constitutively expressed. Stimuli that lead to long-term facilitation perturb the balance between CREB1-mediated activation and CREB2-mediated repression, through the action of PKA, MAPK, and possibly other kinases. This leads to the up-regulation of a family of immediate early genes. Some of these immediate early genes are tran-

scription factors such as C/EBP; others are effectors, such as ubiquitin hydrolase, and contribute to consolidation by extending the inducing signal or by initiating the changes at the synapse that cause long-term facilitation.

Stable long-term facilitation is associated with the synthesis of "late" as well as "early" proteins and with the laying down of new synaptic connections

In addition to ApC/EBP induction, expression of a number of other genes is altered in the sensory neurons of the gill-withdrawal reflex after exposure to repeated pulses of serotonin or long-term behavioral training (Barzilai et al., 1989; Castellucci et al., 1988). One of the early effector

genes is ubiquitin C-terminal hydrolase (Hegde et al., 1997). This rapidly induced gene encodes an enzyme that associates with the proteasome and increases its proteolytic activity. This regulated proteolysis is essential for long-term facilitation: Inhibiting the expression or function of the hydrolase blocks induction of long-term but not short-term facilitation. Thus, through induction of the hydrolase and the resulting up-regulation of the ubiquitin pathway, learning recruits a regulated form of proteolysis that removes inhibitory constraints on long-term memory. One of the substrates of ubiquitin-mediated proteolysis is the regulatory subunit of PKA, degradation of which leads to a persistently active PKA (Chain et al., 1999). This persistence in PKA activity continues for up to 24 hours even in the absence of cAMP or serotonin (Greenberg, Bernier, and Schwartz, 1987) and is essential for the consolidation of short- to long-term memory (Chain et al., 1999).

The stable late phase of long-term facilitation involves the growth of new synaptic connections. In *Aplysia*, Bailey and Chen first demonstrated that long-term behavioral sensitization is accompanied by significant structural changes at the level of identified synapses critical to the behavior. By combining selective intracellular labeling with complete serial reconstructions, they showed that storage of the memory for long-term sensitization is accompanied by a family of morphological alterations at identified sensory neuron synapses. These changes reflect structural modifications at two different levels of synaptic organization: alterations in focal regions of membrane specialization of the synapse (the number, size, and vesicle complement of sensory neuron active zones are larger in sensitized than in control animals) and a parallel but more pronounced and widespread modulation of the total number of presynaptic varicosities per sensory neuron (Bailey and Chen, 1983; Bailey and Chen, 1988). Sensory neurons from long-term sensitized animals displayed a twofold increase in the total number of synaptic varicosities as well as an enlargement in the size of each neuron's axonal arbor. The changes in size and vesicle complement of sensory neuron active zones that were present 24 hours after training did not persist as long as the memory. In contrast, the duration of changes in varicosity and active zone number endured in parallel with the behavioral time course of memory, suggesting that only the increases in the number of sensory neuron synapses contribute to the maintenance of long-term sensitization (Bailey and Chen, 1989).

Aspects of the synaptic growth seen during behavioral sensitization in the intact animal can be reconstituted in dissociated cell culture, where serotonin and cAMP lead to a 50% increase in the number of sensory neuron vari-

cosities. In culture, this increase can be correlated with long-term enhancement of the amplitude of the sensory-to-motor synaptic potential and depends on the presence of an appropriate target cell, similar to the synapse formation that occurs during development (Glanzman, Kandel, and Schacher, 1990). Despite the association of structural changes with different forms of memory storage, surprisingly little is known about the intracellular signaling pathways and molecular mechanisms that convert neuronal activity into the formation of new and persistent synaptic connections. This growth also requires protein synthesis (Bailey, Montarolo, et al., 1992) and is paralleled by the increased expression of late effector genes, which included BiP, calreticulin, and clathrin (Bailey and Kandel, 1993; Hu et al., 1993; Kennedy et al., 1992; Kuhl et al., 1992). In addition, there are proteins whose levels decrease following 5-HT treatment, among them different isoforms of an immunoglobulin-related cell adhesion molecule (apCAM), the *Aplysia* homologue of the vertebrate neural cell adhesion molecule, NCAM and Fasciclin II in *Drosophila*. Light and electron microscopic analysis revealed not only that there is a decrease in the transcription of apCAM during long-term facilitation, but also that ApCAM is removed from the surface membrane of the sensory but not from the motor neuron within 1 hour after the addition of serotonin (Bailey, Montarolo, et al., 1992; Mayford et al., 1992). This rapid, presynaptic down-regulation of cell adhesion molecules is achieved by a transient activation of the endocytic pathway, leading to a protein synthesis-dependent internalization of apCAM and its rerouting from a pathway of apparent recycling to a pathway that seems destined for degradation (Bailey, Chen, et al., 1992). Reduction of the membrane concentration of ApCAM by serotonin may represent one of the early molecular steps required for initiating learning-related growth of synaptic connections. Indeed, blocking apCAM mAbs triggers defasciculation, a step that appears to precede normal synapse formation in *Aplysia* (Glanzman, Kandel, and Schacher, 1989; Keller and Schacher, 1990).

To further define the mechanism whereby serotonin leads to apCAM down-regulation, Bailey and colleagues (1997) used epitope tags to examine the fate of the two apCAM isoforms (membrane-bound and GPI-linked) and found that only the transmembrane form is internalized (figure 9.5). This internalization was blocked by overexpression of transmembrane apCAM with a point mutation in the two MAPK phosphorylation consensus sites, as well as by injection of a specific MAPK antagonist into sensory neurons. These data suggest that activation of the MAPK pathway is important for the internalization of apCAMs and may represent one of

the initial stages of learning-related synaptic growth in *Aplysia*. Furthermore, the combined actions of MAPK both in the cytoplasm and in the nucleus suggest that MAPK plays multiple roles in long-lasting synaptic plasticity and appears to regulate each of the two distinctive processes that characterize the long-term process: activation of transcription and growth of new synaptic connections.

The differential down-regulation of the GPI-linked and transmembrane forms of apCAM raises the interesting possibility that learning-related synaptic growth in the adult may be initiated by an activity-dependent recruitment of specific isoforms of cell adhesion molecules. In conjunction with the recruitment of the family of CREB isoforms described previously, this may provide a regulatory unit capable of acting sequentially at multiple nuclear, cytoplasmic, and plasma membrane sites during the early, inductive phases of the long-term process.

Modulation of cell adhesion molecules appears to be a general mechanism in long-lasting forms of both developmental and learning-related synaptic plasticity (for review see Rutishauser, 1993; Doherty, Fazelli, and Walsh, 1995; Fields and Itoh, 1996; Martin and Kandel, 1996). Thus, in forms of learning and memory in other animals, such as passive avoidance learning, in which chicks learn to suppress pecking behavior toward a bead that is coated with a bitter-tasting liquid, the synthesis of new cell adhesion molecules appears to be critical (Landmesser et al., 1992; Tang, Landmesser, and Rutishauser, 1992). Relatedly, spatial learning and LTP are impaired in NCAM knockout mice (Lüthi et al., 1994). Furthermore, increases in the expression of polysialylated NCAM and in the extracellular concentration of NCAM have been observed after hippocampal LTP, and LTP is inhibited by the application of NCAM antibodies, by NCAM-blocking peptides, or by the removal of polysialic acid by neuraminidase (Rose, 1995). Addition of polysialic acid to NCAM may be functionally equivalent to the internalization of apCAM that occurs

in *Aplysia* neurons in that both processes promote defasciculation, thereby allowing for the growth of new synaptic connections.

Synapse-specific, transcription-dependent plasticity

The finding that long-term memory requires alterations in gene expression poses a cell biological paradox in the study of memory. Does the requirement of transcription and thus the nucleus—a resource shared by all the synapses within a cell—for long-lasting synaptic plasticity mean that long-lasting memory needs to be cellwide, or can the strength of individual synaptic connections be modified independently?

That *synapse-specific* transcription-dependent plasticity does occur has been argued from both theoretical and empirical points of view. Theoretically, since each neuron has a single nucleus but up to thousands of synapses, having the unit of memory storage be the synapse and not the nucleus would greatly maximize the computing power of the brain. Empirically, behavioral studies of classical conditioning in *Aplysia* have shown that there is response specificity in conditioning of the withdrawal reflex (Hawkins et al., 1989). Thus, the gill- and siphon-withdrawal reflex of *Aplysia* undergoes classical conditioning of its amplitude and duration when siphon stimulation (the conditioned stimulus) is paired with tail or mantle shock (the unconditioned stimulus). Whereas the unlearned response to siphon stimulation is straight contraction, the response to tail shock is backward bending, and the response to mantle shock is forward bending. After training for classical conditioning, there is a significant, pairing-specific tendency for the direction of the response to the conditioned stimulus to resemble the response to the unconditioned stimulus (figure 9.6). While this response specificity could be accounted for by branch-specific, activity-dependent facilitation of individual sensory neurons contacting different motor neurons, it is also possible that the response specificity results from facilitation of distinct populations of sensory and motor neurons. Studies in the rodent hippocampus have also shown pathway specificity for the transcription-dependent form of LTP. Thus in “two-pathway” experiments, in which one pathway receives high-frequency stimulation and the other pathway is unstimulated, transcription-dependent LTP is restricted to the tetanized pathway, indicating that it has input specificity (Nguyen, Abel, and Kandel, 1994; Frey and Morris, 1997). However, these studies are at the level not of the single cell, but of populations of cells, and thus the problem of synapse specificity could be solved by recruiting different populations of neurons.

To address these questions at the level of a single cell, Martin, Casadio, and colleagues (1997) modified the

FIGURE 9.5 Differential down-regulation of the GPI-linked versus transmembrane isoforms of apCAM. (A) Neurite of a sensory neuron expressing the GPI-linked isoform of apCAM following a 1-hr exposure to 5-HT. Note that virtually all the gold complexes remain on the surface membrane with none inside, despite a robust 5-HT-induced activation of the endosomal pathway leading to significant accumulations of internal membranous profiles. (B) Neurite of a sensory neuron expressing the transmembrane isoform of apCAM following a 1-hr exposure to 5-HT. In contrast to the lack of down-regulation of the GPI-linked isoform, 5-HT has a dramatic effect on the transmembrane isoform of apCAM removing most of it from the surface membrane, resulting in heavy accumulations of gold complexes within presumptive endocytic compartments. Scale for A and B = 0.25 μm . (From Bailey et al., 1997)

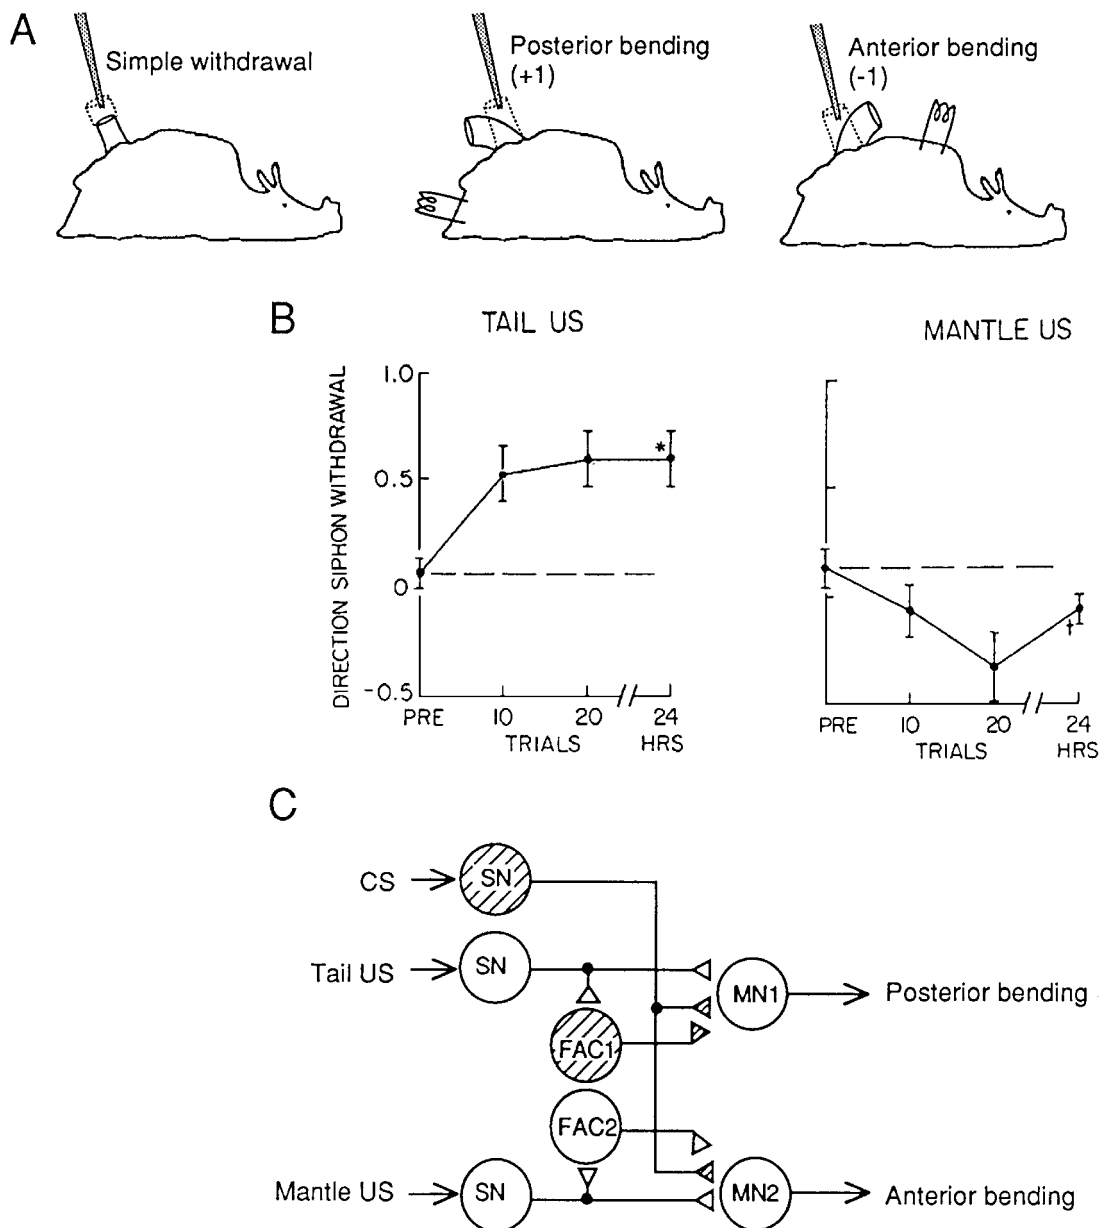

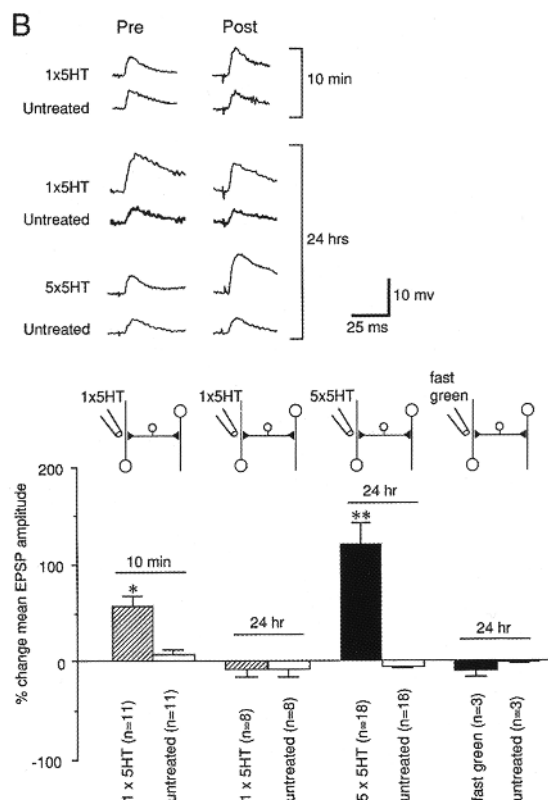

FIGURE 9.6 Response specificity in conditioning of the siphon-withdrawal reflex. (A) In naive animals, siphon stimulation causes straight contraction of the siphon, tail stimulation causes backward bending, and mantle stimulation causes forward bending. During testing, straight contraction was scored as 0, backward bending was scored as +1, and forward bending was scored as -1. (B) Experiment 1. Different animals received training with siphon stimulation as the CS either paired

(P) or unpaired (UP) with tail or mantle shock as the US. The data points indicate the mean direction of siphon withdrawal in response to the CS at each test, and the error bars indicate the SEM. The horizontal dashed line shows the average direction of responding in the pretest (PRE). Significant differences between paired and unpaired training are indicated by an asterisk ($p < .05$) or dagger ($p < .05$, one tailed). (From Hawkins et al., 1989.)

Aplysia culture system by plating a single sensory cell that has a bifurcated axon such that each branch makes synaptic contact with one of two spatially separated motor neurons (figure 9.7). The sensory cell forms stable synapses with each of the motor neurons in culture, and, if serotonin is bath applied to the culture dish, both synaptic connections are strengthened. The advantage of having the synaptic connections spatially separated,

however, is that serotonin can be applied selectively, using perfusion microelectrodes, to the connections made onto a single motor cell, with perfusion of the bath solution adjusted such that neither the sensory cell body nor the connections made onto the second motor neuron are exposed to the serotonin.

As shown in figure 9.7, local application of a single pulse of serotonin onto one set of synaptic connections

produced a transient facilitation of that synaptic connection without any change in synaptic strength at the synapse that was not exposed to serotonin. Thus, one local application of serotonin produced synapse-specific short-term facilitation, as has previously been demonstrated in the intact ganglion (Clark and Kandel, 1993). To examine long-term facilitation, Martin, Casadio, and colleagues (1997) applied five spaced pulses of serotonin to one of the branches. The treated branch showed long-term facilitation: When measured 24 hours later, repeated serotonin application was found to increase the mean EPSP amplitude of the treated synapse without having any effect on the untreated synapse (figure 9.7). A single presynaptic cell can thus undergo long-lasting facilitation that is branch specific. Long-lasting, branch-

FIGURE 9.7 Synapse-specific short-term and long-term facilitation. (A) Serotonin was applied locally to the synaptic connections formed onto one motor neuron using a perfusion microelectrode. Bulk flow of the perfusate prevented the cell body of the sensory neuron or the synaptic connections made onto the other motor neuron from being exposed to the serotonin. A dye (0.05% fast green) was included to visualize the serotonin perfusion. (B) Application of a single pulse of serotonin increased the amplitude of the EPSP at the serotonin-treated branch 10 min after serotonin application without changing the EPSP at the untreated branch (* $p < .05$, change in EPSP amplitude in serotonin-treated versus untreated branch, Student's t -test). This facilitation was transient: There was no increase in the EPSP at 24 hr at either the serotonin-treated or the untreated branch. In contrast, local perfusion of five spaced pulses of serotonin onto one set of synapses produced long-term facilitation of the EPSP at the serotonin-treated branch without any change at the untreated branch (** $p < .01$, change in EPSP amplitude in serotonin-treated versus untreated branch, Student's t -test). In control experiments, perfusion of the dye alkane (fast green) did not change the EPSP at the perfused or the nonperfused branch. Shown are representative recordings of EPSPs and a histogram of the mean change in EPSP amplitude \pm SE. (From Martin, Casadio, et al., 1997)

specific facilitation has recently been reported in the intact ganglion as well (Gooch and Clark, 1997).

This branch-specific facilitation is dependent on transcription, since it can be blocked by actinomycin D, a transcriptional inhibitor, and by injection of anti-CREB antibodies into the sensory cell body. Thus, a single cell can undergo synaptic plasticity that is both synapse specific and dependent on transcription, specifically on CREB-mediated transcription. Furthermore, this branch-specific facilitation is accompanied by the branch-specific growth of new synaptic connections: Imaging of carboxyfluorescein-filled sensory neurons before and after synapse-specific application of 5 pulses of serotonin reveals the growth of new synaptic varicosities at the serotonin-treated but not at the untreated branch.

How might the products of gene expression be targeted to specific synapses and not others? One possibility is that synapses are "tagged" by synaptic stimulation to capture products of gene expression that are exported throughout the cell but are only functionally incorporated at synapses tagged by previous activity. Experimental support for possible synaptic tagging during learning-related plasticity recently emerged from studies of long-lasting LTP in the hippocampus (Frey and Morris, 1997). The studies were based on populations of neurons and synapses and indicated that, with appropriate timing of activity, the products of the gene expression induced by strong stimulation of one set of synaptic connections can be "captured" by another set of synaptic connections that have been tagged by stimuli that normally produce just

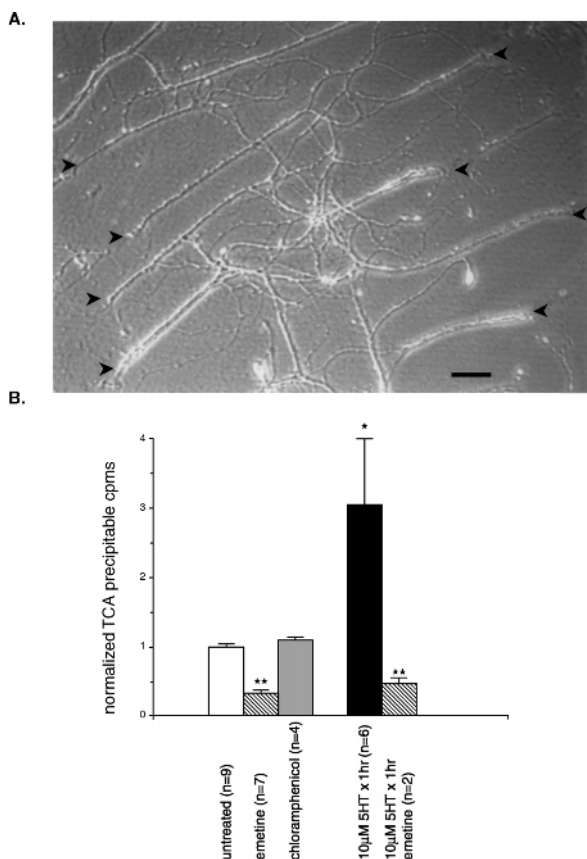

FIGURE 9.8 Translation in isolated presynaptic sensory cell neurites is induced by serotonin. (A, B) Sensory cells (30–40) were cultured for five days. The cell body of each neuron was removed, and the processes were labeled with ^{25}S methionine. Emetine (200 μM) and chloramphenicol (100 μM) were present for 30 min prior to and during the metabolic labeling, and serotonin (10 μM) was present during the metabolic labeling. The cells were then TCA precipitated, and the TCA-insoluble counts were counted on a scintillation counter. Total cpm were divided by the number of cells in each dish. Shown is a histogram of the mean counts plus SE, normalized to the counts in the untreated dishes. The mean cpm/untreated cell was 5.922 ± 1.541 , $*p < .05$, serotonin treated versus untreated processes; $**p < .01$, emetine treated versus untreated and chloramphenicol treated processes, ANOVA followed by Newman-Keul's multiple range test. (From Martin, Casadio, et al., 1997.)

transient LTP. Martin, Casadio, and associates (1997) performed a similar synaptic capture experiment in our system by giving a single application of serotonin, which produces only transient, short-term facilitation, immediately following five pulses of serotonin to the other synapse, and found that this protocol produced long-lasting facilitation at both branches. Thus a single pulse of serotonin appeared to mark the second set of synapses so that they could capture the products of gene expression induced by five pulses of serotonin at the first set of synapse.

What is the nature of the synaptic tag? One characteristic was that it involved the local synaptic translation of mRNAs. Components of the translational machinery including mRNAs and ribosomes have been detected in the distal processes of invertebrate neurons (Crispino et al., 1997; Scheller et al., 1982; Van Minnen et al., 1997), and an intermediate form of facilitation has been described at the *Aplysia* sensory-to-motor neuron synapse that requires translation but not transcription (Ghirardi, Montarolo, and Kandel, 1995). By locally applying protein synthesis inhibitors, Martin, Casadio, and associates (1997) found that the establishment of synapse-specific long-term facilitation was dependent on local protein synthesis in the sensory but not in the motor neuron. In fact, they found that sensory neuron axons whose cell bodies had been removed were capable of protein synthesis, and that this protein synthesis was stimulated threefold by exposure to serotonin (figure 9.8). This finding adds a new function to the actions of neurotransmitters in the nervous system: the regulation of local protein synthesis to establish synapse-specific changes in synaptic strength.

What these studies begin to indicate is that different temporal and spatial patterns of stimulation can recruit different forms of CREB-mediated transcription-dependent long-term facilitation. Are these differences due to events at the synapse or to differences in gene expression? Future experiments in this system promise to provide answers to many of these questions. The convergence of these cellular and molecular studies with genetic and behavioral studies in *Drosophila* and mice are likely to provide a clearer understanding not only of learning and memory, but of a number of other physiological and pathological phenomena in the brain that are believed to involve changes in synaptic plasticity, including activity-dependent development of the nervous system, age-related memory loss, dependence on and tolerance to drugs of abuse, and epilepsy.

10 Memory Consolidation and Long-Term Potentiation

GARY LYNCH

ABSTRACT The relationship of long-term potentiation (LTP) to memory is examined with regard to the phenomenon of consolidation, a poorly understood process whereby newly encoded material is gradually made resistant to disruption. Results and ideas from four areas of work are reviewed. First, in vivo and in vitro studies of rat hippocampus have shown that LTP has a consolidation period with many of the same features, including time course, as those classically described for memory. Second, LTP consolidation appears to be mediated by adhesion chemistries and, in particular, by the activation of latent integrin receptors. These discoveries led to the hypothesis that transmission and adhesion—the two functions of synapses—interact, respectively, to express and consolidate potentiation. Third, certain patterns of neuronal activity associated with learning erase potentiation during the consolidation period. This finding raises the possibility that the consolidation period has psychological utility, perhaps with regard to sculpting newly encoded memories. Fourth, recently invented drugs that promote LTP consolidation reduce the number of training trials needed for the formation of lasting memory. These drugs constitute a first application of information about LTP to development of potential therapeutics for memory impairments. In all, the multiple correspondences between physiological and behavioral consolidation point to the conclusion that the two phenomena have the same substrates.

Much, indeed very much, has been written about the relationship between long-term potentiation (LTP) and memory. Clearly some biological mechanism exists with the rapid onset, longevity, and remarkable capacity of memory; that LTP has these and other useful and uncommon encoding properties made inevitable its investigation as a substrate for long-lasting memory, especially in the absence of alternative proposals. Experimental work began with NMDA receptor antagonists (Morris et al., 1986), moved on to correlational analyses using patterned stimulation as a discriminative cue (Roman, Staubli, and Lynch, 1987), and then turned to molecular biological/behavioral approaches (e.g., Mayford, Abel, and Kandel, 1995). Much has been gained from these efforts, including an appreciation of the profound intellectual and practical difficulties attendant to testing the simple proposition “LTP is a substrate of memory.” To

note a small example with big consequences, substituting the definite article in this proposition converts it to a form that is manifestly *not* true (it is easily shown that forms of memory exist that do not involve LTP) and yet is widely employed, perhaps unwittingly, in LTP/behavior arguments. These difficulties provide ample reason to be pessimistic about the still popular search for an *experimentum crucis* that “proves” or “disproves” the role of LTP in memory. Testing nontrivial or, better still, counterintuitive predictions arising from the memory/LTP hypothesis is a better strategy: it is less method driven, is likely to generate discoveries about the capabilities of brain networks, and satisfies the normal requirements for accepting (rejecting) a hypothesis.

Testing predictions has, in fact, already uncovered a number of intriguing synaptic phenomena. The LTP-as-memory hypothesis requires synaptic potentiation (like memory) to have multiple decay rates, one of which must be extraordinarily slow. These points have been confirmed: LTP has variants lasting for minutes, hours, and days and, in some circumstances persists without evident change for weeks (Staubli and Lynch, 1987). That naturalistic patterns of stimulation (discussed later) can modify synaptic physiology for periods far longer than the half-life of synaptic proteins is remarkable by any measure. The present review begins with another strong and by no means intuitive prediction of the hypothesis. As has probably been known for as long as people have thought about such things, newly formed memory passes through a period during which it is easily erased and after which it is extremely stable. Consolidation, the name given to the stabilizing process, places severe constraints on LTP as a memory substrate: (a) potentiation has to be erasable without disturbing transmission at neighboring connections; (b) vulnerability has to be time dependent; (c) the pertinent time period should align with that for stabilization of memory. It bears emphasizing that these predictions about LTP arise solely from behavior—there is nothing in neurobiology that necessitates selective vulnerability or specifies the time frame over which potentiation fades. The first section of this chapter, “Consolidation of LTP,” deals with results

from experiments directed at the three consolidation predictions.

Relationships between macroscopic and microscopic levels of inquiry, as in the case under discussion, are most fruitful when they run in both directions. The “downward” portion of the dialogue is realized in the constraints imposed by the macroscopic level upon the nature of the microscopic, examples of which have been noted for memory/LTP. The “upward” portion has both familiar and not so familiar components. Regarding the former, mechanistic explanations for macroscopic phenomena are acknowledged goals of multilevel studies; in the present context, LTP research began with the assumption that isolation of the substrates of potentiation would yield satisfactory cellular explanations for specific aspects of memory. The second section, “Mechanisms: The adhesion hypothesis of consolidation,” will ask if it has fulfilled this expectation with regard to consolidation. The less discussed aspect of the upward side of dialogue (from the micro- to the macro-) concerns understanding or awareness of the phenomena associated with memory. Does LTP predict the existence in memory of phenomena that have gone unnoticed or least under appreciated? This need not be the case. Potentiation isn’t isomorphic with memory, and its neurobiological richness might not include details indicative of undiscovered counterparts in psychology. But maybe it will, and a potential case specific to consolidation is described in the third section, “Does the consolidation period have psychological utility?”

The preceding arguments are illustrated in figure 10.1 along with two additional, somewhat more pragmatic, motives for thinking about LTP from a psychological perspective. The first involves “synaptic memory algorithms” for network simulations. These operating rules relating input variables to when, where, and the degree to which contacts will change can be empirically derived through LTP experiments. Work along these lines has yielded novel algorithms and some impressive examples of computation with biological networks. Memory-enhancing drugs are a second potential by-product of LTP research. Potentiation of a preselected set of synapses in an *in vitro* environment is a much more tractable test system for drug development than behavior. According to the LTP hypothesis, compounds that promote stable potentiation are likely to have positive effects on consolidation of memory. This line of thought led to the discovery of a new class of drugs, and results obtained with these form the fourth subject considered here, in “The pharmacology of consolidation.”

Consolidation of LTP

The idea that LTP has a memory-like consolidation period began with the startling (at least to the investigators)

FIGURE 10.1 The dialogue between memory and long-term potentiation (LTP). Memory describes features in potentiation that need to be found before a causal relationship can be assumed (downward arrow). LTP provides explanations for various features of memory—for example, why new memories take minutes, rather than seconds or hours, to stabilize. The upward leg of the dialogue also involves asking if features in LTP can be used to illuminate features of memory that have gone unnoticed. Uncovering nontrivial phenomena often plays an important role in the process whereby microscopic/macroscopic linkages become accepted. Also shown in the figure are two pragmatic advantages in studying LTP and memory together. Potentiation is more easily used than behavior in developing memory-related drugs and provides direct access to the network-level learning rules needed for simulations of brain systems.

discovery in 1980 that potentiation, generated with high-frequency bursts in anesthetized rats, disappears if low-frequency afferent stimulation is applied within a few minutes of induction (Barriónuevo, Schottler, and Lynch, 1980). Too little was known in those early days of LTP to allow for educated guesses as to what types of processes might be involved in the reversal, but three additional observations limited the range of possibilities. First, the effect is synapse specific in that reversing LTP does not disturb neighboring contacts. This result indicates that reversal, like LTP, depends on local biochemical events. Second, reversing stimulation has only transient effects when applied to unpotentiated synapses, indicating that the chemistries triggered by the stimulation interact with those earlier set in motion during the induction of LTP. Third, normal-sized LTP was readily elicited after reversal, as expected if all traces of prior potentiation had been eliminated by the low-frequency stimulation. All three results are explained by the assumption that reversal works by interrupting still active synaptic processes that would (unless disturbed) ultimately produce stable LTP.

A subsequent chronic recording experiment confirmed these points and showed that LTP does not spon-

taneously recover even after delays of 24 hours (see figure 10.2), again indicating that potentiation was fully erased by low-frequency stimulation (Staubli and Lynch, 1990). The chronic study also showed that the stimulation needed for reversal does not create physiological disturbances in freely moving rats (Staubli and Lynch, 1990). This result reinforced the impression from the earlier, acute experiments that reversal, or at least the activity patterns causing it, could be occurring routinely during behavior. Discussion of this idea will be resumed in a later section.

The first in vitro studies of consolidation deliberately mimicked paradigms used in behavioral studies; that is, a global condition that disrupts physiology was administered at various intervals after LTP had been induced. Hypoxia of a duration just sufficient to transiently block synaptic responses completely eliminated LTP when ap-

plied within the first minute after induction but had only a momentary effect on neighboring, control synapses. Potentiation was resistant to hypoxia applied 30 minutes after induction; indeed, prolonging the episodes to the point at which pathophysiology appeared failed to affect LTP (Arai, Larson, and Lynch, 1990). These results established that LTP has a consolidation period and, moreover, that *the duration of this period is not greatly different than that expected from studies of memory consolidation*. They also prompted efforts to induce LTP reversal in slices using the low-frequency stimulation patterns that had proven effective in animals. Success in this (Larson, Xiao, and Lynch, 1993) made it possible to finally carry out parametric studies of stimulation patterns and to address the all-important question, from the perspective of the memory/LTP hypothesis, of how closely the time course for LTP stabilization matches that for consolidation. The

FIGURE 10.2 Low-frequency stimulation erases recently induced long-term potentiation. Chronic recording from freely moving rats was used to test whether LTP reappears once it has been reversed. Two collections of afferents (Schaffer-commissural projections) within the hippocampus were independently stimulated with single pulses at two times per minute. Average response size over two days of testing (days -2 and -1) was used as a baseline. On the experimental day, responses were collected for 15 min, after which "theta bursts" were applied to one of the two outputs. Low-frequency stimulation was applied

within 5 min of LTP induction. The second pathway (open circles) served as a control for any generalized effects of repetitive stimulation. Recording was continued for an hour and the rats returned to their home cages. One day later (day +1), they were returned to the recording apparatus, and tests were made to determine whether LTP had returned. No evidence for spontaneous recovery was found. A second round of theta bursts was then administered. As shown, LTP comparable to that seen 24 hr earlier was obtained. (Modified from Staubli and Lynch, 1990.)

latter issue was taken up by Ursula Staubli and colleagues (Staubli and Chun, 1996); their results along with those from the first memory consolidation experiment (Duncan, 1949) are shown in figure 10.3. The agreement between curves constitutes a striking example in which an otherwise arbitrary property of memory is paralleled in LTP. “Otherwise arbitrary” because there are no known biological or psychological processes that would dictate the illustrated time course for consolidation. Changes in gene expression, for example, are too slow to explain a process that is well under way within a minute and results in an extremely stable state 15–30 minutes later.

An additional point established in the *in vitro* studies is that reversal can be modulated. Specifically, the probability and magnitude of the effect were increased by high concentrations of norepinephrine (Larson, Xiao, and Lynch, 1993) while the postinduction time frame for robust reversal was substantially lengthened by positive modulators of AMPA-type glutamate receptors (Staubli and Chun, 1996). Independent of their significance for ideas about the substrates of reversal, these results showed that the LTP consolidation period has

some of the same flexibility as its counterpart in memory.

Mechanisms: The adhesion hypothesis of consolidation

What is it, then, that stabilizes LTP and, by inference, memory? Figure 10.4 suggests an answer by recalling that synapses (the locus of potentiation) are junctions with two functions, one highly specialized and the other ubiquitous. The specialized activity–transmission–is the subject of much of neurobiology, while the commonplace function–adhesion–is all but ignored. The simple proposal to be made here is that these functions interact—that transmitter receptors modify adhesion receptors, and adhesion receptors, through their control of junctional organization, regulate the status of transmitter receptors.

INTEGRINS AND CONSOLIDATION Adhesion chemistries were brought into LTP (Staubli, Vanderklish, and Lynch, 1990; Xiao et al., 1991) as a mechanism that

FIGURE 10.3 Memory and LTP consolidate over the same time period. The behavioral data are from Duncan’s original description of the time course for consolidation, submitted in April 1948 (Duncan, 1949). Those studies used electroconvulsive shocks (ECS) to disrupt recent learning; that is, rats were trained, given ECS, and tested for retention on the following day. As shown, ECS applied immediately after learning essentially erased memory; the amnesic effect became progressively smaller as the interval between learning and ECS was increased to 5 min, although consolidation did not appear to

be complete even at 15 min. Numerous examples of consolidation over this time frame, though often without the steepness of the curve shown here, have been published. The LTP data are from a paper by Staubli and Chun (1996). In this instance, low-frequency stimulation was delivered at various times after LTP had been induced (see figure 10.2) and the amount of potentiation 45 min later tested. Near complete erasure was obtained when the stimulation was given after a delay of 30 seconds; longer delays resulted in progressively less reversal. Note again that consolidation is not quite complete even at 15 min.

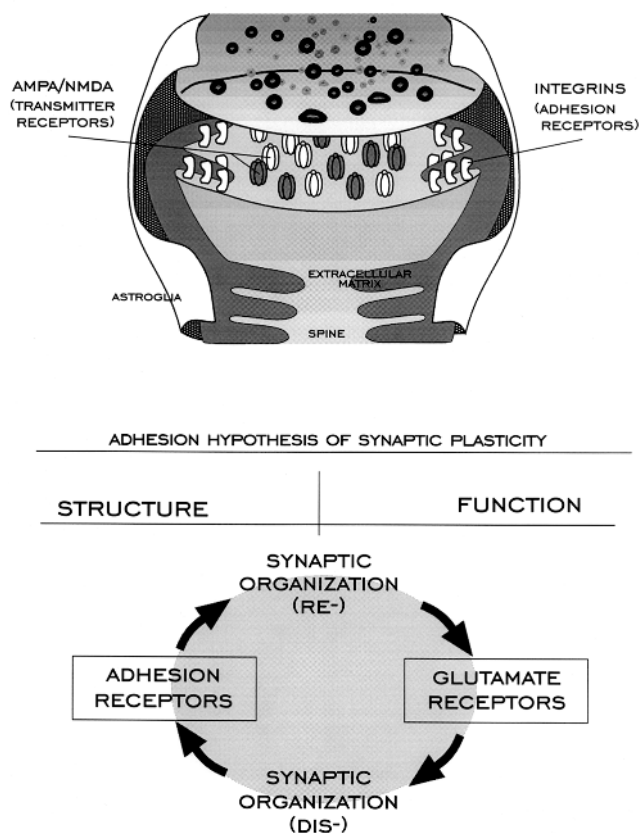

FIGURE 10.4 The adhesion hypothesis of consolidation. The figure in the upper panel emphasizes the usually overlooked point that synapses have two very different functions—transmission and adhesion—requiring very different types of receptors. The illustrated ingredients have been described in experimental reports from different laboratories, but the arrangement here is hypothetical. Integrins are shown binding to the extracellular matrix, some part of which is probably generated by the surrounding sheets of astroglial processes. Cadherins and neural cell adhesion molecules, two other types of adhesion receptors found in synapses, are not included in the figure. The bottom panel summarizes the proposal that the two classes of receptors interact, with the result being expression and consolidation of LTP. Glutamate receptors are pictured as driving intracellular chemistries that disassemble the synaptic cytoskeleton and existing adhesive relationships. This process activates latent adhesion receptors that over several minutes reorganize the cytoskeleton and restabilize the synapse. Remodeling the synapse in this way affects the environment in which AMPA-type glutamate receptors are situated; this effect, according to this hypothesis, changes the operating characteristics of the receptors and thus the size and shape of synaptic currents.

could account for three earlier observations: (1) Potentiation is accompanied by changes in synaptic morphology that develop within minutes but then persist indefinitely (Lee et al., 1980, 1981). (2) Consolidation is largely complete within 30 minutes (see preceding sec-

tion). (3) The minimal stimulation needed to induce potentiation causes partial cleavage of cytoskeletal proteins (see Vanderklish et al., 1995, for direct tests). The first two points required a minutes-range chemistry that can shape morphology into new and stable configurations; the third described how extant structures could be disassembled and indicated that reassembly would have to work on an altered cytoskeleton. Integrins, one of three classes of transmembrane cell adhesion receptors, have properties that match up well with these requirements. They exist in latent states and are brought into play by the sorts of transient events (Du et al., 1991; Newton, Thiel, and Hogg, 1997, for examples) associated with LTP induction; once activated they assemble a remarkable collection of cytoplasmic proteins and thereby reorganize the submembrane cytoskeleton (see Clark and Hynes, 1996, for a review). The time course for this is on the order of several minutes (e.g., van Willigen et al., 1996)—ideal for consolidation—and has as its consequence the formation or modification of a junction that will persist for long stretches of biological time unless actively disturbed.

The first tests for the involvement of integrins in LTP consolidation took advantage of the critical discovery that binding of many of the receptors to their matrix targets is blocked by short peptides containing the amino acid sequence RGD (Pierschbacher and Ruoslahti, 1984). Such peptides block integrin-mediated events (e.g., fibroblast attachment, platelet aggregation, etc.) throughout the body (e.g., Haskel and Abendschein, 1989) and proved to be effective in blocking the consolidation of LTP (Staubli, Vanderklish, and Lynch, 1990; Xiao et al., 1991). Not unexpectedly, given that integrins don't mediate moment-to-moment activities, the antagonists had no measurable effects on baseline physiology, the burst responses used to induce LTP, or the initial degree of potentiation. Nonetheless, LTP induced in their presence failed to stabilize but instead decayed steadily toward baseline over a period of 60 minutes. Later work tested whether integrin activation satisfies one of the most stringent demands that consolidation places on potential substrates, namely, reversal of already established potentiation. Experiments directed at this issue showed that RGD-containing peptides selectively reverse LTP when infused 2 minutes after induction but not when applied after delays of 25 min or longer (figure 10.5). Intermediate results were obtained with applications at 10 min (Staubli, Chun, and Lynch, 1998). The agreement in time courses over which low-frequency stimulation and highly selective peptide antagonists (whose effect is eliminated by single amino acid substitutions) reverse LTP strongly suggests that the two manipulations have a common target. *Integrin activation/engagement thus emerges as that process whose temporal requirements dictate the*

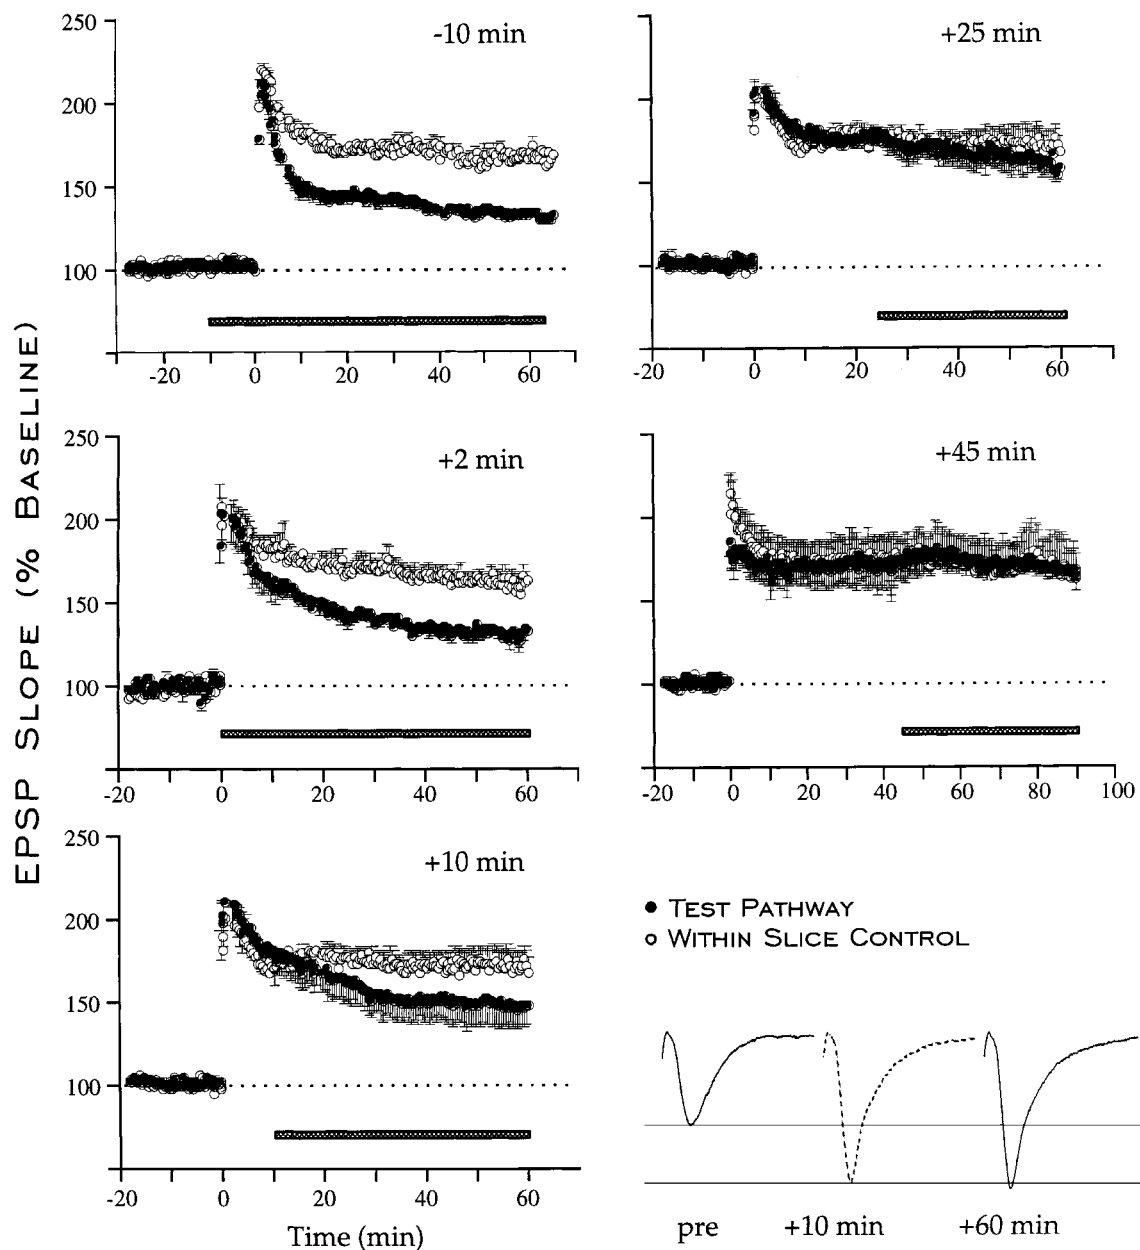

FIGURE 10.5 Integrin receptor antagonists block consolidation. This experiment parallels that summarized in figure 10.3. The antagonists were locally applied to sites within hippocampal slices at various times before or after LTP induction. Controls (open circles) in this case consisted of sites within the slice

particular time courses recently discovered for LTP and repeatedly described for memory.

Two further points should be noted before leaving the topic of integrin antagonists and physiology. First, a mechanism has been identified that explains how low-frequency synaptic responses could block integrin activation; this is considered in a later discussion on the pharmacology of consolidation. Second, RGD peptides block the development of kindling in hippocampal slices (Grooms and Jones, 1997). This recent and important

at which LTP was induced but antagonist was not applied. Blocking integrins even 10 min after induction prevented consolidation. The same treatment had no evident effect when administered 25 min after LTP had been established. (Modified from Staubli et al., 1998.)

discovery adds a second case in which integrins appear to translate transient high-frequency activity into very stable physiological changes; it will not be surprising if other examples follow.

The results on adhesion and LTP set in motion a search for synaptic integrins in the adult brain. There was virtually no information on this topic at the time of the initial physiological studies, but biochemical experiments soon established that RGD-binding integrins are highly concentrated in forebrain connections (Bahr,

FIGURE 10.6 Brain regions differ in the types of integrins they express. Shown are the distributions of a subgroup of the mRNAs encoding different α subunits used in forming dimeric integrin receptors. Panels A, B, and C show that integrins are differentially expressed across hippocampal subdivisions; CA3

has $\alpha 1$, while dentate gyrus has $\alpha 7$ and CA1 has enriched $\alpha 8$. Regional differences are also found in the cerebellum where $\alpha 3$ is located in the Purkinje neurons while $\alpha 7$ is present in the granule cells. (See Pinkstaff et al., 1999, for further description.)

Sheppard, and Lynch, 1991; Bahr and Lynch, 1992; Bahr et al., 1997). Immunohistochemical work took this investigation much further by localizing known integrin subunits to spines and postsynaptic densities in the hippocampus (Einheber et al., 1996; Nishimura et al., 1998; also see Grooms, Terracio, and Jones, 1993). With the discovery that synapses have integrins, the question of whether different regions or types of neurons utilize different versions of the receptors assumed some importance. Integrins are dimers composed of combinations drawn from more than 16 known α subunits and at least 8 β subunits. Variations in subunit composition have a large effect on the properties of the assembled $\alpha\beta$ integrins; peripheral tissues take advantage of this fact to

generate collections of functionally distinct adhesion receptors. Recent studies mapping the distribution of the mRNAs encoding the different subunits strongly suggest that brain regions do the same. An example for one subunit is shown in figure 10.6. If these differences are reflected in assembled integrins, then variations in synaptic adhesion receptors would likely be as great as or greater than differences in transmitter receptors. This possibility has important implications for ideas about regional specializations for plasticity and consolidation.

MECHANISMS FOR MODIFYING SYNAPTIC ADHESION. Results connecting integrins to consolidation were followed by reports that cell adhesion molecules (CAMs)

and cadherins, the other two classes of adhesion receptors, are also involved in LTP (Rønn et al., 1995; Luthi et al., 1994; Tang, Hung, and Schuman, 1998). These reports provided additional support for, and greatly extended, the general hypothesis that adhesion chemistries are responsible for LTP consolidation. In the case of CAMs, it appears that the relevant changes occur quickly, since blocking agents have little effect when applied immediately after induction (Rønn et al., 1995; Staubli, Chun, and Lynch, 1998). In all likelihood, the three classes of adhesion receptor differ with regard to the following: (1) steps needed to dismantle extant adhesive contacts; (2) steps required to reestablish the contacts; and (3) the influence of the new linkages on emerging changes in synaptic organization and function. In accord with their functions in other systems, and as confirmed by the time course over which their antagonists reduce recent LTP, integrins have a central role in organizing stable changes in the synaptic cytoskeleton and the morphology it supports. The other adhesion receptors minimally provide attachment sites to stabilize remodeled connections and could participate in more active, but so far unknown, ways (point 3).

Regarding disruptive steps (point 1), intracellular proteolysis by calpain (a calcium-sensitive cysteine protease) coupled with extracellular proteolysis by released serine proteases (Hoffman, Larson, et al., 1999; Hoffman, Martinez, and Lynch, 1999) appear to be critical for consolidating LTP. Both types of enzymes are known to recognize an array of proteins that participate in junctional adhesion (Sheppard et al., 1991; Du et al., 1995; Hoffman, Larson, et al., 1999) and therefore have the potential to disengage the adhesive relationships supported by all three classes of receptors. The breakdown products generated by the proteases appear immediately after inducing stimulation but do not increase in concentration thereafter (Vanderklis et al., 1995; Hoffman, Larson, et al., 1999). This finding indicates that the proteolytic events themselves are very brief and restricted to a fraction of the adhesion-related proteins; a limited degree of disengagement can be assumed.

Finally, engaging latent receptors, as discussed for integrins, may not be available to the other two groups of adhesion molecules as a means of reestablishing contacts. Other options include inserting new copies drawn from a local pool, provided by ongoing synthesis, or generated by up-regulating synthesis. Thus there is an interesting possibility that consolidation of synaptic changes is only partially complete after integrins have been activated and synaptic anatomy reorganized. Complete stabilization may come only when cleaved proteins have been replaced and the remodeled synapse left with a normal complement of adhesion molecules. Re-

placement, protein synthesis, and consolidation are considered again in a later section.

CONNECTING CONSOLIDATION AND EXPRESSION. Stable LTP requires both consolidation and expression events—that is, a change that lasts indefinitely (or is periodically renewed) and a modification to transmission that increases the size of postsynaptic currents. Given that the generators of these currents are continuously broken down and replaced, it is difficult to envision the two functions emerging from a single cellular change. If so, then links between consolidation events and expression events are needed. Links, of course, can only be considered in the context of what has been learned about the basis of expression, aspects of which are noted in the following paragraphs.

An extensive body of evidence points to changes in the AMPA-type glutamate receptors that mediate fast synaptic currents (EPSCs) throughout the brain as the agency of LTP expression:

Argument by exclusion

1. LTP occurs without changing frequency facilitation (Muller and Lynch, 1989) or the effects of other manipulations that influence release probability (Muller et al., 1988). The lack of interaction makes it extremely unlikely that potentiation itself affects probability.

2. Normal LTP can be induced with minimal (Muller, Joly, and Lynch, 1988; Muller and Lynch, 1988) or no (Kauer, Malenka, and Nicoll, 1988) changes in NMDA-receptor-gated currents. NMDA and AMPA receptors are colocalized in synapses; short of a set of unlikely assumptions, it is difficult to picture how changes in transmitter concentration could affect one group of receptors and not the other. These widely replicated results are in accord with the preceding point and rule out changes in transmitter release as the expression mechanism.

3. A change in the thickness of the spine neck is a rare unitary explanation for consolidation and expression; that is, a change that is structural, and therefore could last for as long as the synapse itself, causes a decrease in resistance to synaptic current. Elegant as the idea is, tests of two predictions arising from it proved negative (Jung, Larson, and Lynch, 1991; Larson and Lynch, 1991).

If LTP is not expressed by increases in transmitter or decreases in postsynaptic resistance, then by exclusion it is very probably due to receptor modifications.

Plausibility AMPA-type glutamate receptors, which mediate the synaptic responses that become potentiated, are unusually “plastic.” Removing the receptors from their synaptic membranes causes them to shift to a much

higher affinity state (Hall, Kessler, and Lynch, 1992), something that does not occur with NMDA receptors. Various experiments indicate that they are influenced by phospholipids (Massicote et al., 1991), intermolecular associations with other proteins (Terramani et al., 1988; Hall et al., 1996), and subsynaptic enzymes (Strack et al., 1997; Barria et al., 1997; Hayashi et al., 1997). In light of these findings, it can be expected that changes in the membrane environment arising from remodeled synaptic anatomy will change the receptors responsible for fast synaptic currents. AMPA receptors are thus plausible candidates for the site of expression.

Correlational evidence

1. Receptor biophysics dictate the shape as well as the size of synaptic current. Changes in waveform are therefore expected for many, but not all, types of receptor modifications. A particular type of waveform shift has in fact been found in studies using field potential (Ambros-Ingerson et al., 1991, 1993; Ambros-Ingerson and Lynch, 1993) or whole-cell recording from slices (Xie et al., 1997), and is evident in data from single-synapse recordings (Stricker, Field, and Redman, 1996; see Kolta, Lynch, and Ambros-Ingerson, 1998).

2. Modifications to receptor biophysics because of LTP should change the effects of other manipulations that independently alter biophysics. This relationship has been confirmed (Xiao et al., 1991; Staubli, Ambros-Ingerson, and Lynch, 1992; Kolta, Lynch, and Ambros-Ingerson, 1998) using the drug aniracetam, which slows certain AMPA receptor rate constants (Ito et al., 1990). The result has been disputed (Asztely et al., 1992) and in any event should be revisited with much more potent AMPA receptor modulators that have recently become available (see the section "Ampakines" below). The point is crucial for two reasons: (1) Interactions between LTP and modulatory drugs would be presumptive evidence that potentiation had modified the operating characteristics of AMPA receptors; (2) coupled with waveform change data, the nature of the interactions could be used to define the nature of the modifications.

Receptor manipulation If AMPA receptors are the agents of expression, then modifying their makeup should in some way modify LTP. This idea was tested using translational suppression of a single receptor subunit to shift receptor composition in favor of the remaining subunits (AMPA receptors are pentamers or tetramers). This experiment was feasible because fully functional AMPA receptors assemble in the absence of the targeted, normally present subunit (Hollman and Heinemann, 1994; see Seeburg, 1993, for reviews). As expected, there were no apparent changes in baseline physiology in slices

with reduced concentrations of the subunit. Expression of LTP, however, was drastically reduced (Vanderklish et al., 1992).

Various proposals based on the evidence summarized here have been made regarding the nature of the receptor change responsible for expression. These include the following:

More receptors The presence of more receptors could be due to the activation of latent receptors or the insertion of copies from a free pool (Lynch and Baudry, 1984, and others). Increases in receptors would almost certainly increase post-synaptic currents.

Clustering Modeling studies by Berger and colleagues suggest that clustering would modify the probabilities of transmitter binding in such a way that a potentiated response would eventuate (Xie et al., 1997).

Modulatory proteins Reorganizing the subsynaptic cytoskeleton could increase the access of proteins that modulate the operational characteristics of AMPA receptors.

Membrane environment As noted, the receptors are very sensitive to their protein and lipid environment, which itself is influenced by the submembrane structural proteins; changing the environment as part of synaptic remodeling would modify receptor biophysics or conductance.

The first two ideas do not involve changes in receptor properties, but the second two do; accordingly, proposals three and four predict interactions between LTP and modulatory drugs, whereas one and two do not. There are already data on this point. The third and fourth ideas can be further tested by defining enzyme and/or lipid influences on the receptors in reduced systems and then searching for comparable effects after LTP induction. Separating the first and second ideas could in principle be done with binding studies (more receptors, more sites). However, past experiments of this type have yielded contradictory results, leaving the question open. Further studies of this kind, together with those on the other listed possibilities, should result in a leading candidate for the mechanism of expression.

Returning to the question of links between consolidation and expression, each of the four expression proposals involves a passive response to a structural change. For example, it is easy to envision a more circular postsynaptic apposition zone increasing the area available for receptors; ongoing processes that insert receptors into the zone would then, without changing their operations, create LTP. Similar morphofunctional arguments can be made for how shifts in the configuration of the subsynaptic cytoskeleton necessarily will influence receptor density, synaptic membrane fluidity,

and the movement of modulatory proteins from the spine cytoplasm to the inner face of the synaptic membrane. A very attractive feature of these ideas is that they separate the problem of extreme stability—as manifested by LTP and memory—from the need to adjust the operation of transient receptors. However, it must be stressed that the sequence composed of adhesion chemistry → synaptic morphology → receptor operation, though biologically plausible, remains a hypothesis that posits yet-to-be-demonstrated connections between three independent groups of results. It is for future studies to describe, for example, the connections between adhesion receptors and the postsynaptic density or between the postsynaptic density and clustering of AMPA receptors.

Does the consolidation period have psychological utility?

The memory/LTP hypothesis predicts that naturally occurring patterns of brain activity, as well as patterns related to learning in particular, induce the potentiation effect. The discovery that this is in fact the case (Larson and Lynch, 1986; Larson, Wong, and Lynch, 1986) provided one of the more convincing links between memory and potentiation. The pertinent work has been reviewed elsewhere and will only be noted here as necessary background to a seldom-asked question about consolidation posed by studies on LTP reversal.

A 4–7 Hz rhythm (theta) occurs throughout the cortical telencephalon and is particularly prominent in the hippocampus of small mammals during active behavior. Individual cells commonly emit short bursts of high-frequency activity (3–4 pulses in 30–50 ms) with the bursts being synchronized with the rhythm (Otto et al., 1991). These conditions (bursts separated by 150–250 ms) proved to be ideal for inducing LTP when used as a stimulation pattern. Studies on the reasons for this result showed that theta takes advantage of an IPSP refractory process that reaches its maximum at about 200 ms (Larson, Wong, and Lynch, 1986). Theta thus momentarily releases target neurons from feedforward inhibition (Larson and Lynch, 1986), allowing a second theta burst to generate depolarization sufficient to activate NMDA receptors (Larson and Lynch, 1988) and produce the elevations of internal calcium needed to induce potentiation. Other workers found that the refractory period itself is due to inhibition of GABAergic terminals by GABAB autoreceptors (Mott and Lewis, 1991). In all, the investigations of the LTP-theta relationship provided a first success in coupling brain rhythms to synaptic chemistry. Moreover, the connection of patterns of brain activity with increments in synaptic strength provided

mechanistic explanations for fundamental features of memory including the prominence of temporal contiguity in the forming of associations.

The fact that LTP induction has a deep relationship with a particular rhythm inevitably raised the question of whether this is also true for LTP reversal. Confirmation came in a series of experiments using hippocampal slices (Larson, Xiao, and Lynch, 1993). While the existence of particularly appropriate patterns for reversal was not unexpected, it was indeed surprising that the pertinent rhythm proved to be theta. This discovery strongly implies that erasure requires the prolonged EPSPs that result from IPSP suppression, presumably for altogether different reasons than those involved with induction. Possible mechanisms suggested by theta and other aspects of reversal will be taken up briefly in a later section. But independent of neurobiological issues, the connection of reversal to a prominent rhythm points to the possibility that it is a “real world” event, that is, one that occurs routinely in behaving animals. This impression is strengthened by a more detailed examination of the experiments in which the connection was found. Two inputs (groups of Schaffer-commissural fibers) that converged on a target population of dendrites were used (figure 10.7). Pairs of theta bursts were applied simultaneously to each input; 20 seconds later, *single pulses* at 5 per second (theta) were delivered to one of the two inputs for 30 seconds. This procedure was repeated every 2 minutes for a total of five pairs of theta bursts. Absent theta pulse stimulation, both inputs increment their synaptic strength after each pair of theta bursts until a ceiling is reached after 5–10 pairs; with the pulses, one input grows stronger and the other does not change (see Larson, Xiao, and Lynch, 1993). These results establish that reversal is synapse specific (neighboring inputs were unaffected), occurs with small fiber populations, and involves a commonplace rhythm. Thirty sequential pulses are not likely to occur in vivo, but there is no reason to assume that fewer pulses would not be at least partially effective (30 was the lowest number used in the Larson, Xiao, and Lynch studies). It is also the case that, anecdotally at least, reversal is more robust in vivo than in vitro. In all, conditions needed for reversal may occur routinely during behavior.

The vulnerability of memory to disruption during consolidation is not usually thought of with regard to its psychological utility. But the demonstration that near-normal physiologies can eliminate newly induced synaptic changes is certainly suggestive of a kind of “active forgetting.” Something like this could be useful in focusing memory on essential features by erasing over trials the aspects of information that are not reliably detected in successive samplings. Forming a composite memory

FIGURE 10.7 Naturally occurring patterns of afferent activity block consolidation. The illustrated experiments showed that the theta rhythm erases LTP as well as inducing it. Theta burst pairs were delivered simultaneously to two small group of afferents that converged on a population of target neurons (top panel). One population (Pathway 2) received theta pulses be-

ginning 30 seconds later; the other population (Pathway 1) did not. This procedure was repeated five times at 2-min intervals. As shown in the bottom panel, robust and stable LTP developed in Pathway 1, while Pathway 2 was barely changed. (Modified from Larson, Xiao, and Lynch, 1993.)

of a building from different viewpoints could be an example. In any event, the idea that memories are being continuously made and discarded using two versions of the same rhythm (theta bursts, theta pulses) has consequences for network theories, the design of memory-enhancing drugs, and learning theory.

Active forgetting provides a first example in which LTP research suggests something about memory that has not been prominent in psychological studies or theories (the second of the upward links noted in the introductory paragraphs). Moreover, the idea arrives with details that would not have been found with behavioral analyses alone but that nonetheless have behavioral connotations. Theta pulses are an example: these are not detectable as such in behavior but are probably closely associated with a subset of psychological states (Vertis and Kocsis, 1997). Information of this sort not only fleshes out the idea of active forgetting but also provides a correlational approach for testing if it exists; for example, does the presence or absence of the pulses correlate with what is learned (e.g., the steepness of generalization gradients for a complex cue). Pharmacological manipulation provides another approach with which to search for active forgetting, but this is better considered in the general context of LTP and memory enhancement (see the next section). Finally, it bears repeating that the uncovering of interesting phenomena in response to developments at a more microscopic level of analysis has historically proved to be a critical step in the acceptance of theories about mechanisms. In this sense, reversal and forgetting may contribute to the debate on LTP and memory.

The pharmacology of consolidation

Long-term potentiation seen from the perspective of psychology is primarily a tool for explaining and illuminating memory. As noted in the introductory paragraphs and considered here, it can also serve as a test bed with which to develop drugs directed at consolidation.

THREE CLASSES OF SYNAPTIC RECEPTORS The assumption that consolidation involves the sequence “glutamate receptors → adhesion receptors → glutamate receptors” defines two interactions (→) that are obvious targets for memory-enhancing drugs. Figure 10.8 describes another set of possibilities. As illustrated, synapses contain modulatory receptors in addition to the already discussed transmitter and adhesion receptors. There are a variety of these but the two included in the figure—adenosine and platelet-activating factor (PAF) receptors—are of particular interest because they have potent and opposite effects on LTP. Adenosine appears to

THE SYNAPSE: A JUNCTION WITH THREE TYPES OF RECEPTORS

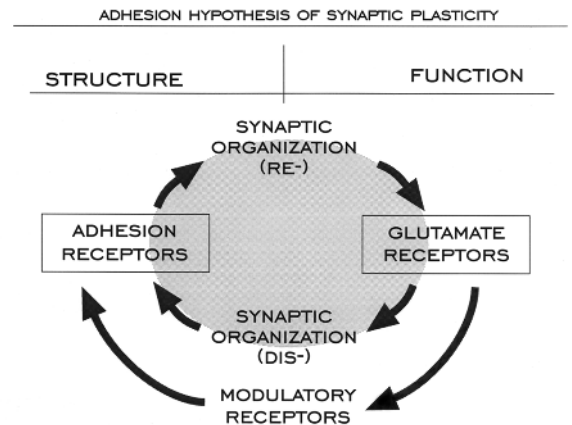

FIGURE 10.8 Incorporating modulatory receptors into the adhesion hypothesis of consolidation. Three types of receptors reported to be present in synapses are shown in the top panel. Possible relationships between them, and how these might influence consolidation, are considered in the bottom schematic. Glutamate receptors are postulated to relax synaptic organization by activating calcium-dependent, intracellular enzymes and to indirectly generate agonists (e.g., adenosine, platelet activating factor) for the modulatory receptors. The modulatory receptors then act on adhesion chemistries engaged by the relatively sudden loss of synaptic organization. The return link (adhesion to transmission) is discussed in the text (also see figure 10.4).

drive the reversal effect: stimulating the receptors immediately after induction reverses LTP (Arai, Kessler, and Lynch, 1990) while blocking them protects consolidation from hypoxia (Arai, Larson, and Lynch, 1990) or theta pulses (Larson, Xiao, and Lynch, 1993; Staubli and Chun, 1996; Abraham and Huggett, 1997). Add the observation that low-frequency stimulation causes a sizable efflux of adenosine (Cunha et al., 1996), and the case for adenosine reversal seems quite good. This opens up the possibility of using centrally active adenosine-receptor antagonists to search for traces of LTP reversal and active forgetting in behavior. Such studies would have to confront a lack of data on the synaptic effects of antago-

nists in vivo and, as well, develop controls for their notable peripheral influences. With regard to consolidation, any positive effects of adenosine-related drugs would probably come at the expense of what may be a psychologically useful reversal process.

PAF is a potent ether phospholipid that plays a prominent role in inflammatory cascades; it is rapidly generated from brain membranes under a variety of circumstances (see Bazan et al., 1997, for a review). The presence of high-affinity PAF receptors in synaptic membranes (Marcheselli et al., 1990) pointed to the possibility that PAF generated during intense activity somehow contributes to plasticity. This suspicion was confirmed in studies showing that PAF-receptor antagonists block the stabilization of LTP (del Cerro, Arai, and Lynch, 1990; Arai and Lynch, 1992; Bazan et al., 1997). Currently there are no compounds that promote PAF-receptor operations or that would otherwise positively influence the links between synaptic activity, PAF genesis, and PAF-receptor stimulation. Absent these, there are no obvious ways in which PAF's contributions to consolidation can be exploited in developing memory-enhancing drugs.

In passing it should be noted that the opposing effects of PAF and adenosine on LTP, which otherwise have no a priori basis, fit well within the adhesion hypothesis of consolidation. PAF receptors are among the most common triggers for converting latent integrins into an active configuration (Newton, Thiel, and Hogg, 1997)—activation, it will be recalled, was the minutes-long event proposed to reorganize (and restabilize) synaptic morphology. Adenosine receptors, however, are the only receptors so far described that *retard* the engagement of previously latent integrins (Theil et al., 1996). While these results point to the modulatory arrangements diagrammed in figure 10.8, it remains to be established that adenosine and PAF relationships described for peripheral tissues also hold for the brain in general and synapses in particular.

Returning to adhesion and transmitter receptors, there are no compounds available that selectively manipulate the engagement of integrins or facilitate the indirect influence they are postulated to exert on glutamate receptors. The same can be said of the other adhesion molecules (NCAMs, cadherins) and their related chemistries. This situation could change—the study of the links between synaptic adhesion and synaptic plasticity is only just under way, and interest is steadily increasing. But for now, the most obvious route for enhancing LTP is to modulate positively the transmitter receptors that set consolidation chemistries in motion. The obvious problem here is that the receptors mediate the most basic of brain operations with plasticity being a secondary issue.

However, selectivity may not be quite the problem it seems. (1) Prolonged depolarizations are needed for LTP induction, something that afferent bursts produce with strings of closely spaced EPSPs. Temporal summation is critical in that individual EPSPs must persist long enough so that depolarization is maintained, and deepened, by the arrival of the next EPSP. Drugs that extend the duration, but not the amplitude, of the EPSP will have their greatest effects when the responses are not truncated by IPSPs (as they normally are)—that is, during theta pattern activity. It may be possible, then, to develop positive modulators that have larger effects on LTP induction than on baseline transmission. (2) Enhancing excitatory receptors could have a normalizing rather than a disruptive influence when transmission is depressed. This occurrence is likely in humans, a species in which substantial losses of excitatory synapses in cortex are a normal aspect of aging (Masliah et al., 1994). These arguments prompted efforts to design and synthesize centrally active positive modulators of glutamate receptors. As described in the next subsection, the resultant compounds have the predicted memory-enhancing properties.

AMPAKINES Ampakines have no agonist/antagonist effects in excised patches but instead enhance the response of AMPA receptors to glutamate (figure 10.9). This process involves at least two actions: (1) a slowing of the rate at which the receptor channels stop opening—"desensitize"—in the continuing presence of agonists and (2) reducing the speed with which currents return to baseline—"deactivation"—following a 1-millisecond agonist pulse (Arai et al., 1994, 1996). An effect on opening/closing rates is also possible. The effects of the modulators on deactivation are more predictive of their synaptic actions than are their effects on desensitization (Arai and Lynch, 1998).

The drugs cause a rapid increase in the duration of AMPA-receptor-mediated synaptic responses in hippocampal slices (Staubli et al., 1994) and do so at the same concentrations that enhance AMPA-receptor-gated currents in excised patches. They enter the brain within a minute of interperitoneal injections, prolong the duration of excitatory synaptic responses, and markedly facilitate the induction of LTP in freely moving rats (Staubli, Rogers, and Lynch, 1994). The details of this last result are of interest. Theta bursts with sub-optimal numbers of pulses were used to induce a variant of LTP that gradually decayed to baseline over several hours; that is, the initiating conditions were insufficient to produce stable (consolidated) potentiation. Several days later the rats were retested after having been given the ampakine. The same stimulation now

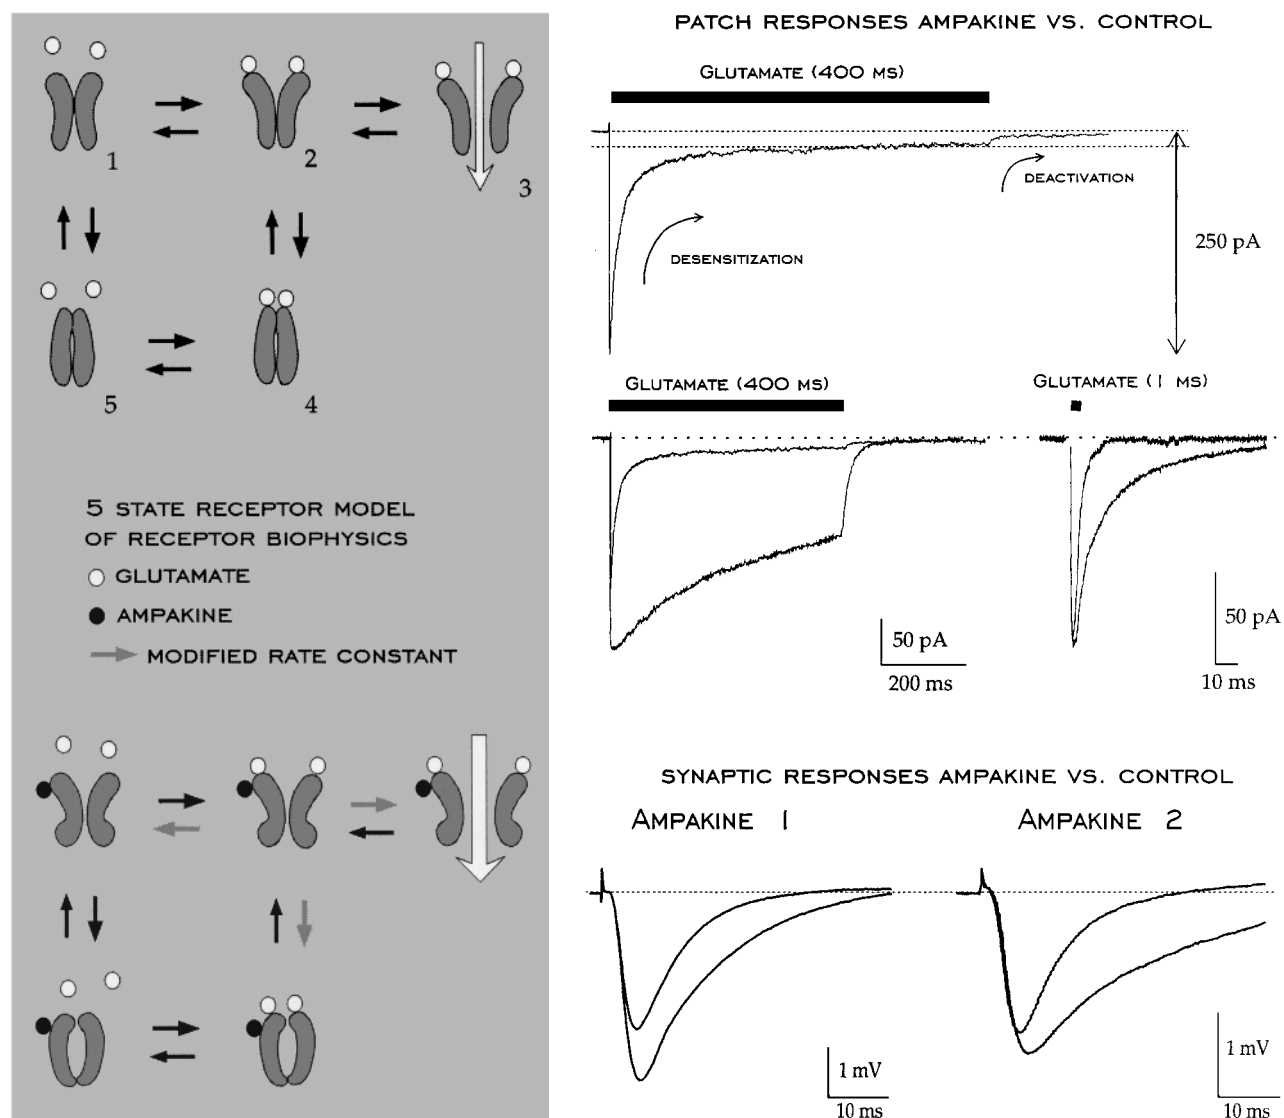

FIGURE 10.9 Centrally active drugs that positively modulate AMPA-type glutamate receptors. The right-hand side shows effects of ampakine drugs on excised patches and hippocampal slices. The top panel is a patch response to a 400-ms application of glutamate. Note that the response drops precipitously despite the continuing presence of agonist. This pattern is “desensitization.” The current also takes several milliseconds to return to baseline after glutamate is washed free; this delay is referred to as deactivation. The middle panels describe the effects of an ampakine on patch responses. Desensitization is partly blocked as evidenced by the massive increase in current flow during the sustained application (left side). Responses to 1-ms pulses are shown to the right; under these conditions, which are reasonably close to those obtaining at synapses, it is evident that the ampakine reduces the rate of deactivation. The effects found with brief glutamate pulses are mirrored in synaptic responses, as can be seen in the bottom two tracings.

Results for two ampakines are shown to illustrate that the drugs are not entirely homogeneous in their effects: note that ampakine 1 has a large effect on the amplitude of the response while ampakine 2 increases its duration. Deduced effects of the drugs on the operations of AMPA receptors are illustrated with the models on the left. The five states in the model are (1) receptor baseline; (2) receptor with bound transmitter; (3) receptor opens; (4) desensitized receptor with bound transmitter; (5) desensitized receptor with transmitter dissociated. Ampakines have no effect on the receptor until a binding event (transmitter release) occurs. According to simulation studies, one mode of action that would account for the observed effects on patches and synaptic responses is a reduction in the rate constants (arrows) leading away from state 2. This would allow the receptors to open and close for a longer-than-normal period and thereby increase net current flow. (See Aria et al., 1994, 1996, for further description.)

produced LTP that persisted without evident change for the several hours of the recording session; it thus appears that the positive modulator allowed a marginal degree of theta-driven depolarization to cross the threshold for triggering consolidation chemistries.

Tests for the effects of ampakines on memory consolidation were carried out using a two-odor discrimination task in which well-trained rats typically need ~10 trials to acquire memories that persist for at least three days. A within-subject design was used such that the same rats were given 5 training trials with and without prior administration of an ampakine. The dosage used had no effect on speed of performance or other measures sensitive to arousal and motivation; the selective effects of ampakines at moderate doses on behavior have been described across a variety of testing circumstances. Within the olfactory task, retention scores after several days were well above chance for odor pairs learned in the presence of the ampakines and at chance for those acquired without the drugs (Larson et al., 1995). Evidence that ampakines reduce the requirements for long-term memory was also obtained in eyeblink (Shors et al., 1995) and fear (Rogan, Staubli, and LeDoux, 1997) conditioning studies.

Another series of studies resulted in the intriguing idea that ampakines facilitate the acquisition of “strategies,” an extremely stable form of memory. Rats were trained to asymptotic performance on a delayed non-match-to-sample paradigm. Beginning in the fifth week of the study an ampakine was administered on every other day of testing. Scores for the rats improved in small increments over two weeks of treatment with the cumulative increase being large. *These improvements lasted for at least a week after drug injections were stopped (longer times weren’t tested).* Post hoc analyses showed that the ampakine caused a gradual reduction in the proactive interference caused by a certain type of error; that is, errors on a preceding trial had a lesser effect on the current trial (Hampson et al., 1998a). This result presumably indicates that the rats had acquired a between-trials behavior that minimized the disturbing effects of a wrong choice. Unit recording through an array of chronic electrodes showed that between-trial pattern of firing initiated by the pertinent class of error was reduced by the drug treatments (Hampson et al., 1998b), again as expected if the rats acquired new responses for the delay periods after incorrect choices. In all, it appears that ampakines promote the stable encoding of procedures that otherwise would not become established even with extended training.

Results for ampakines in humans are very limited. Nonetheless, positive effects on memory have been noted in tests using nonsense syllables (Lynch et al.,

FIGURE 10.10 Effects of an ampakine on the recall of nonsense syllables by 65–75-year-old subjects. Individuals were given drug or placebo at the indicated doses, read a list of 10 nonsense syllables, and asked to recall as many items as possible after a delay of 5 min. Previously collected data indicated that young adults remember between 4 and 5 syllables. As shown in the figure, older subjects do not do as well. The high concentration of ampakine produced a sizable and statistically significant improvement in retention. It is noteworthy that the effective dose, on a mg/kg basis, was at the lower end of the range of concentrations found to be effective in animal studies. (Modified from Lynch et al., 1997)

1997) as well as more complex measures (Ingvar et al., 1997). The improvements recorded for a small population of elderly subjects were particularly striking (figure 10.10; Lynch et al., 1997). If these results are replicated, then ampakines would constitute a first successful extension of what has been learned about LTP to the development of memory-enhancing drugs.

Summary

The similarities between consolidation of LTP and consolidation of memory described in this chapter are indicative of a very close relationship. The biochemistries recently found to subserve the physiological phenomenon are therefore in all probability the same as those that stabilize newly encoded memory. If so, then the extraordinary 50-year search for the chemistry of consolidation, a scientific episode notable for its singular hypotheses, will in the end have led to the same types of chemistries that mediate such prosaic events as blood clotting. Linking LTP, in all of its specifics, to consolidation also points to new things to look for in memory. One possibility—sculpting recently acquired memory—was discussed and others could have been cited.

Further insights into memory and its consolidation can be expected as more is learned about the adhesion chemistries that appear to stabilize potentiation. Major

issues here include the identity of the enzymes that activate latent receptors—a list that presumably includes certain of the lipases and kinases already implicated in LTP—and how modified adhesion affects synaptic architecture and, ultimately, the operation of transmitter receptors. Information on these points is essential for filling out and testing what is now a very sketchy version of an adhesion hypothesis for LTP. It could as well provide a new generation of pharmacologies with which to explore the extent to which consolidation at the behavioral level uses the same cellular processes as physiological consolidation. Of particular relevance to ideas about memory storage is the question of whether the pronounced regional differences in adhesion receptors translate into regional specializations for synaptic plasticity. Analysis of this topic could be a first step in a neurobiological approach to the long-standing questions of whether and by what means brain systems encode qualitatively distinct forms of memory.

A still largely unexplored LTP question with special relevance to the history of consolidation research concerns the cellular events that follow the ~30-minute period during which memory and LTP become firmly entrenched. Beginning with the first years of the field and continuing since, reports have appeared that protein- or RNA-synthesis inhibitors eliminate new learning, in some cases when applied hours or days after training. This often controversial line of work gave rise to the idea that consolidation continues for some time after initial stabilization. If, as current evidence indicates, formation of the lasting variety of LTP requires intracellular and extracellular proteolysis, then the final version of potentiated synapses probably, but not certainly, requires newly synthesized protein. Cytoskeletal and adhesion proteins cleaved during induction presumably must be replaced either from existing pools, by ongoing synthesis, or via up-regulation at transcriptional and/or translational levels. Experiments showing that intense afferent activity increases levels of various mRNAs after about 15 minutes suggest that links with gene expression are available to triggers for LTP. Several studies have tested for contributions by protein synthesis to LTP with positive results (Stanton and Sarvey, 1984; Deadwyler, Dunwiddie, and Lynch, 1987; Nguyen, Abel, and Kandel, 1994; Frey and Morris, 1998); however, various problems, including the potential for unrecognized disturbances to the physiologies that induce potentiation or transmission, underlie the issue.

The argument that synthesis is vital to an hours- or days-long process of completing a remodeled connection raises the issue of whether the new proteins are simply replacement copies for those cleaved during the disassembly phase or instead are in some way novel.

This latter idea of potentiation does not appear to add anything useful to the “disassembly (proteolysis) → reassembly (integrins) → replacement (synthesis)” version of consolidation. This is not to say that neurons and glia lack specialized synthetic machinery used in restabilizing synapses and consolidating potentiation. Dendritic mRNAs encoding cytoskeletal proteins and astroglial genes for matrix proteins are examples of strategically located synthetic systems that could quickly provide substitutes for partially cleaved intra- and extracellular synaptic proteins. But rather than being specialized memory molecules, the proteins in question are better thought of as elements in the brain's version of a general system for modifying and sustaining adhesion junctions. While perhaps lacking the excitement sometimes found in the literature on proteins and memory, this formulation moves the problem closer to areas in which much is known and progress is rapid.

11 Trophic Interactions and Neuronal Plasticity

ERIC S. LEVINE AND IRA B. BLACK

ABSTRACT Increasing evidence suggests that trophic interactions that influence brain ontogeny mediate processes as diverse as learning, memory, and regrowth after injury. This chapter describes recent insights suggesting that impulse activity regulates availability of neurotrophic factors, which in turn modulate neuronal morphology and efficacy of synaptic communication. Through these processes, millisecond-to-millisecond signaling can be converted into long-term changes in neural circuit architecture and function. In addition, different excitatory transmitter receptor subtypes subserve trophic or regressive effects, enabling a neural system to memorialize excitatory or inhibitory experiences precisely. Thus signaling mechanisms that participate in the formation of neuronal circuits during development appear to operate throughout life to modulate interneuronal communication. A variety of open questions are delineated to define provisional future directions.

Emerging evidence suggests that mechanisms underlying developmental plasticity play roles throughout life. For example, processes as diverse as learning, memory, and regrowth after injury may be mediated by cellular and molecular mechanisms that also govern normal development of the nervous system. Commonality of mechanism is exemplified by the increasing awareness of the multiple, critical functions served by brain growth and survival (trophic) factors.

Although growth and survival factors have been the focus of study in developmental biology for decades, their critical roles throughout life have been appreciated only recently. Yet growth factors appear to occupy a central functional niche, potentially integrating experience, impulse activity, synaptic pathway formation (and plasticity), and neural circuit architecture during maturity as well as development. Moreover, traditional distinctions among growth factors, trophic factors, and neurotransmitters are dissolving. To provide perspective for these new views, it may be helpful to summarize salient char-

acteristics of the now-classical agent, nerve growth factor (NGF).

The pioneering studies of Levi-Montalcini, Hamburger, and Cohen established that NGF is required for the survival and normal development of peripheral sensory and sympathetic neurons (Levi-Montalcini and Hamburger, 1953; Cohen and Levi-Montalcini, 1956; Cohen, 1960; Levi-Montalcini and Angeletti, 1968). However, even these initial studies indicated that, in addition to survival, NGF exerted other effects, which could potentially play roles in contexts different from development. For example, the factor elicits neurite outgrowth, and targets treated with NGF become innervated by increased numbers of terminals of responsive neurons (Olson, 1967; Levi-Montalcini and Angeletti, 1968). These experiments clearly suggested that NGF influences neural circuit architecture, at least during development.

The foregoing observations were complemented by the seminal demonstration that target NGF is transported from innervated target to perikarya of innervating neurons in a retrograde fashion (Hendry, Stach, and Herrup, 1974; Hendry et al., 1974; Hendry, 1975). Consequently, NGF may act as a messenger mediating retrograde communication of information from visceral target to innervating neuron in the peripheral nervous system. Since the density of target innervation correlates with the concentration of target NGF messenger RNA (mRNA) (Shelton and Reichardt, 1984), the elaboration of trophic factor by targets may regulate architecture of the pathway and communication between afferent neurons and particular targets.

The recent realization that trophic factors are synthesized in the brain stimulated interest in mechanisms of action and regulation. For example, the observation that NGF regulates the function of basal forebrain cholinergic neurons (Hefti, Dravid, and Hartikka, 1984; Hefti et al., 1985; Martinez et al., 1985; Large et al., 1986; Martinez et al., 1987) and the localization of NGF to hippocampal targets (Whittemore et al., 1986) suggested that trophic functions are critical centrally as well as peripherally. Since the septohippocampal system appears

ERIC S. LEVINE Department of Pharmacology, University of Connecticut Health Center, Farmington, Conn.

IRA B. BLACK Department of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, Piscataway, N.J.

to play an important role in contextual-spatial memory (Eichenbaum, Otto, and Cohen, 1992), trophic and mental functions might somehow be related. Central targets might play roles analogous to those in the periphery, and central interactions might mediate mnemonic function.

The developing trophic field grew more intriguing and complex with the discovery that brain-derived neurotrophic factor (BDNF) and NGF exhibit sequence similarity (Leibrock et al., 1989). The inference that these were members of a neurotrophin gene family was quickly confirmed by the molecular cloning and sequencing of neurotrophin (NT)-3 and NT-4 (Maisonpiere et al., 1990; Hallböök, Ibáñez, and Persson, 1991). Localization of NGF and BDNF, in particular to the hippocampus (Whittemore et al., 1986; Hofer et al., 1990), extended the potential scope of target trophic interactions in the brain.

In turn, critical issues concern the mechanisms that regulate the elaboration of trophic factors by targets, as well as the effects that neurotrophins exert on responsive neurons. Are factors simply produced constitutively by targets, independent of intercellular, environmental stimuli? Alternatively, is expression of trophic factors regulated, potentially allowing the extracellular environment to influence trophic interactions? The latter alternative, of course, may have far-reaching implications, potentially allowing experience to affect trophic interactions, synaptic pathway modulation, and neural communication. Further, if regulation extends beyond development into maturity, environmental influences may access neural pathway architecture throughout life.

A separate issue concerns whether neurotrophins alter pathway efficacy in a dynamic manner. Since such alterations may constitute an important form of plasticity, and even contribute to such critical processes as learning and memory in some systems, trophic modulation of synaptic transmission has attracted increasing attention.

This brief background summary may now permit articulation of some specific questions concerning neurotrophin roles in the brain. Most generally, are trophic gene expression and factor elaboration regulated processes in the brain? Does experience gain access to trophic interactions? More specifically, do pathway use and impulse activity play roles in trophic interactions? Do neurotrophins, in turn, regulate the strength of synaptic communication and neuronal excitability? Which specific transmitter systems and synaptic elements are targeted by neurotrophins? These and related questions have been approached through a combination of *in vivo* and *in vitro* techniques.

Trophic gene expression and the balance between excitatory and inhibitory activity

Although trophic interactions in the brain have been intensely studied for nearly a decade, the relationship of trophic gene expression to neural activity has been approached only recently. Experiments performed *in vivo* initially raised the possibility that innervating neurons might regulate trophic expression in targets. For example, fimbrial transection elevated NGF expression in neonatal hippocampus, suggesting that innervation regulates target elaboration of the trophic factor (Whittemore et al., 1987).

Complementary studies demonstrated that limbic seizures increase hippocampal NGF gene expression (Gall and Isackson, 1989; Gall, Murray, and Isackson, 1991; Isackson et al., 1991). Induction of limbic seizures electrolytically increased NGF mRNA in neurons of the hippocampal dentate gyrus within 1 hour and in neocortical and olfactory forebrain neurons several hours thereafter. Results were quantitated by *in situ* hybridization and nuclease protection. The NGF message decreased from 1.5 to 15 hours after seizure onset, indicating that the elevation was transient, not long-lasting. These observations raised the possibility that increased impulse activity, in this case pathologic, may increase NGF gene expression, either directly or indirectly. The *in vivo* nature of the paradigm, and the widespread nature of limbic seizures precluded more detailed analyses. Other approaches have begun to define mediating mechanisms.

Using cultured hippocampus, as neuronal dissociates in fully defined medium or as explants, direct evidence that depolarization regulates NGF gene expression was obtained (Lu et al., 1991a; Elliott et al., 1994). The depolarizing stimuli, elevated K^+ (35 mM) or the Na^+ channel blocker veratridine, evoked a threefold increase in NGF mRNA (figure 11.1). The effect of veratridine was specifically blocked by tetrodotoxin, which antagonizes the channel-blocking actions of the alkaloid, suggesting that depolarization itself increased NGF gene expression. Moreover, using the hippocampal neuronal dissociates, regulation by intrinsic spontaneous impulse activity was analyzed. To increase spontaneous activity in the cultures, inhibitory gamma-aminobutyric acid interneurons were blocked with picrotoxin. Exposure to picrotoxin elicited nearly a threefold increase in NGF message, suggesting that NGF gene expression represents a balance between excitatory and inhibitory impulse activity (figure 11.2). These studies suggested that depolarizing influences and endogenous impulse activity directly regulate trophic gene expression. One natural next set of questions concerned the specific transmitters involved and the mediating receptors.

FIGURE 11.1 Regulation of NGF mRNA expression in hippocampal neurons by depolarization. E18 hippocampal neurons were cultured for 6 days in serum-free medium. These cultures were then treated with the following agents for an additional 2 days and harvested for NGF mRNA measurement: K^+ , 35 mM; veratridine (Ver), 1 μ M; tetrodotoxin (TTX), 1

μ M. (Upper) Autoradiogram with 40 μ g of total RNA per lane. Arrow indicates the 411-base-pair NGF mRNA fragment protected by RNase T2. (Lower) Densitometric plot of the autoradiogram. The result represents three experiments with independent RNA preparations. (Reprinted from Lu et al., 1991a, by permission.)

Lindholm and colleagues examined a variety of transmitters in cultured hippocampal dissociates (Zafra et al., 1990). Kainic acid, a glutamate receptor agonist, dramatically increased neuronal NGF message. In contrast, *N*-methyl-D-aspartic acid (NMDA) or inhibitors of NMDA glutamate receptors exerted no effects. Further, the kainate effect was blocked by antagonists of non-NMDA receptors, implying that depolarization of hippocampal

neurons by glutamate, through the mediation of non-NMDA receptors, regulates NGF gene expression. The same transmitter-receptor systems also elevated expression of BDNF, suggesting that multiple neurotrophins are regulated by impulse activity in the hippocampus (Zafra et al., 1990).

Recent studies have substantiated this contention and raised the possibility that trophins play roles in

FIGURE 11.2 Regulation of NGF gene expression by spontaneous neuronal activity. E18 hippocampal neurons were cultured in serum-free medium. The control group was cultured for 8 days. The tetrodotoxin (TTX) group was cultured for 2 days and treated with 1 μ M TTX for 6 days. The picrotoxin group was cultured for 8 days and treated with the gamma-aminobutyric acid antagonist picrotoxin (1 μ M) for 6 hours on the last day. All groups were cultured for the same amount of time before harvest for NGF RNase protection. Autoradiograms were analyzed densitometrically, and numerical values were normalized to percentage of control. (Reprinted from Lu et al., 1991a, by permission.)

physiological processes involved in memory. Long-term potentiation (LTP), an activity-dependent enhancement of synaptic transmission, has attracted attention as one potential mechanism underlying memory function (Bliss and Lomo, 1973). Studies have recently implicated trophic interactions in LTP. Induction of LTP in the hippocampal CA1 pyramidal cell layer increased BDNF and NT-3 messages in CA1 neurons (Patterson et al., 1992). The alterations were apparently cell specific, since nonstimulated regions of the pyramidal cell layer and the dentate exhibited no alterations in mRNA. Moreover, NGF mRNA was unchanged. Since trophins are known to increase transmitter levels and induce axon terminal sprouting, the authors speculate that activity-induced increases in trophic expression may play a role in the relatively stable changes in synaptic transmission that occur in LTP. Evidence for this hypothesis is presented in a subsequent section.

Transmitter-trophic interactions exert both progressive and regressive actions

Whereas the foregoing studies indicate that impulse activity may regulate trophic factor gene expression, other evidence suggests that trophic stimulation and neu-

rotransmitters interact to regulate neuronal form and function. One initial indication of transmitter-trophic interactions derived from an unexpected source, the cerebellum. A number of studies indicated that NGF protein (Large et al., 1986), NGF receptor protein (Eckenstein, 1988; Schatteman et al., 1988; Yan and Johnson, 1988), and NGF receptor mRNA (Buck et al., 1988; Schatteman et al., 1988) are transiently expressed in the cerebellum in several species. These observations raised the possibility that NGF regulates the development of some cerebellar populations. The discovery that Purkinje cells in the developing cerebellum *in vivo* express high- and low-affinity NGF receptors identified a key population that might be regulated by the trophic factor (Cohen-Cory, Dreyfus, and Black, 1989). This result was of particular interest, since the development of Purkinje cells was known to be regulated by multiple epigenetic factors (Altman, 1972; Altman and Bayer, 1985), including presynaptic innervation (Berry and Bradley, 1976; Sotelo and Arsenio-Nunes, 1976).

To elucidate mechanisms by which trophic and presynaptic stimulation might regulate ontogeny of Purkinje cells, the effects of NGF and excitatory transmitters on survival and morphological maturation were studied in dissociated cell culture (Cohen-Cory, Dreyfus, and Black, 1991). Simultaneous exposure to depolarizing agents and NGF specifically enhanced Purkinje survival. NGF, in combination with either high potassium or veratridine markedly increased Purkinje survival. Moreover, NGF together with the excitatory presynaptic transmitters aspartate or glutamate increased survival twofold (figure 11.3). NGF also increased Purkinje cell size and promoted neurite elaboration. These effects required simultaneous exposure to NGF and either aspartate, glutamate, or pharmacologic depolarizing agents (figure 11.4). Enhanced survival and neurite elaboration were not elicited by exposure to trophic factor or transmitters alone. These results suggest a novel mechanism in which trophic factor and afferent stimulation interact to promote survival and morphogenesis of developing Purkinje cells (see also Morrison and Mason, 1998). The effects on neurite growth were particularly provocative, since this may be a critical determinant of synaptic connections and circuit architecture. In this system, then, the combined action of transmitter and trophic agent may regulate neural system organization. What mechanisms might mediate transmitter-trophic interactions?

We sought to identify the excitatory amino acid (EAA) receptors involved in the regulation of Purkinje survival (Mount, Dreyfus, and Black, 1993). EAAs activate multiple ionotropic receptors as well as a G-protein-linked "metabotropic" receptor. Ionotropic re-

FIGURE 11.3 Effects of aspartate and NGF on Purkinje cell survival. E18 rat cerebellar cells were grown in culture and immunostained for calcium-binding protein to identify Purkinje cells. Duplicates of two independent experiments were analyzed per condition. Doses of 10 μ M aspartate (Asp) and 200 units/ml NGF were used for the time in culture. Values depicted (mean \pm SEM) are as follows: Control, 100 \pm 4.49%; NGF, 115.0 \pm 6.72%; Asp, 99.75 \pm 8.42%; Asp + NGF, 194.0 \pm 15.70%. The actual number of cells in representative control cultures was 1688 \pm 99.42.* Differs from control, NGF, and aspartate by $p < .05$. (Reprinted from Cohen-Cory, Dreyfus, and Black, 1991, by permission.)

ceptors are composed of three major subtypes, each named for its preferred agonist (the NMDA, quisqualate/AMPA and kainate receptors). Ionotropic and G-protein-linked receptors have been identified on Purkinje cells (Dupont, Gardette, and Crepel, 1987; Garthwaite, Yamini, and Garthwaite, 1987; Sekiguchi, Okamoto, and Sakai, 1987; Linden et al., 1991; Llano et al., 1991; Masu et al., 1991). To ascertain how receptors modulate survival, Purkinje cells were cultured with NGF, and EAA receptor subtypes were selectively stimulated or antagonized.

Initially, we characterized the potential role of ionotropic EAA receptors by exposing cultures to the antagonists MK-801, D-APV (D-2-amino-5-phosphorovaleric acid), and DNQX (6,7-dinitroquinoxaline-2,3-dione). Each increased cell number, suggesting that endogenous ionotropic activity *decreased* survival. To determine whether G-protein-linked EAA receptor stimulation modulates survival, the metabotropic agonist ACPD (1-aminocyclopentane-1,3-dicarboxylic acid) was examined. ACPD alone had no effect on survival. However, simultaneous exposure to ACPD and NGF significantly elevated Purkinje number. Further, increased survival was blocked by the selective metabotropic antagonist L-AP3. In addition, L-AP3 reduced cell number in the absence of exogenous EAA. Thus endogenous metabotropic stimulation is normally necessary for survival.

In sum, excitatory transmitters apparently shape development through a novel mechanism, simulta-

neously exerting trophic actions through G-protein-linked receptors and regressive influences through ionotropic receptors. The ultimate effect of an excitatory transmitter may be determined by the balance between metabotropic-trophic and ionotropic-regressive actions. In the case of Purkinje cells, aspartate, the putative EAA transmitter of innervating climbing fibers, regulates survival through trophic and regressive influences. It is apparent, then, that exquisite precision of regulation may derive from the delicate balance among excitatory, inhibitory, and modulatory actions of transmitters and trophic agents.

Neurotrophins modulate efficacy of synaptic transmission

Recent work indicates that neurotrophins acutely regulate neuronal excitability and synaptic efficacy, greatly expanding potential functional roles. Neurotrophins modulate neuronal activity through multiple mechanisms of action, including induction of ion channel expression, enhancement of presynaptic neurotransmitter release, and modulation of postsynaptic receptor responsiveness. These newly discovered effects have been identified both in the developing and mature nervous systems, indicating that mechanisms responsible for the formation of neural circuits during development also play roles in the dynamic regulation of activity within established circuits.

Neurotrophins can directly regulate neuronal excitability via changes in expression of voltage-gated ion channels. This ability has been most closely examined in PC-12 cells, a pheochromocytoma cell line that differentiates into a sympathetic neuronlike phenotype in response to NGF. In these cells, NGF induces the expression of multiple types of sodium, potassium, and calcium channels (Garber, Hoshi, and Aldrich, 1989; Sharma et al., 1993). The increase in sodium channel expression is mediated at least in part by cyclic AMP-dependent protein kinase (Kalman et al., 1990). Whereas continuous exposure to NGF causes the induction of a family of sodium channels, brief exposure selectively induces expression of the peripheral nerve-type sodium channel gene PN1 (Toledo-Aral et al., 1995). NGF also increases expression of voltage-gated sodium, calcium, and potassium currents in the SK-N-SH neuroblastoma cell line (Lesser and Lo, 1995).

Although these effects have been typically characterized in clonal cell lines, similar mechanisms occur in the brain. One of the best-characterized NGF-responsive cell populations in the brain comprises the cholinergic neurons of the basal forebrain. These neurons provide a dense modulatory input to the hippocampus. Taken

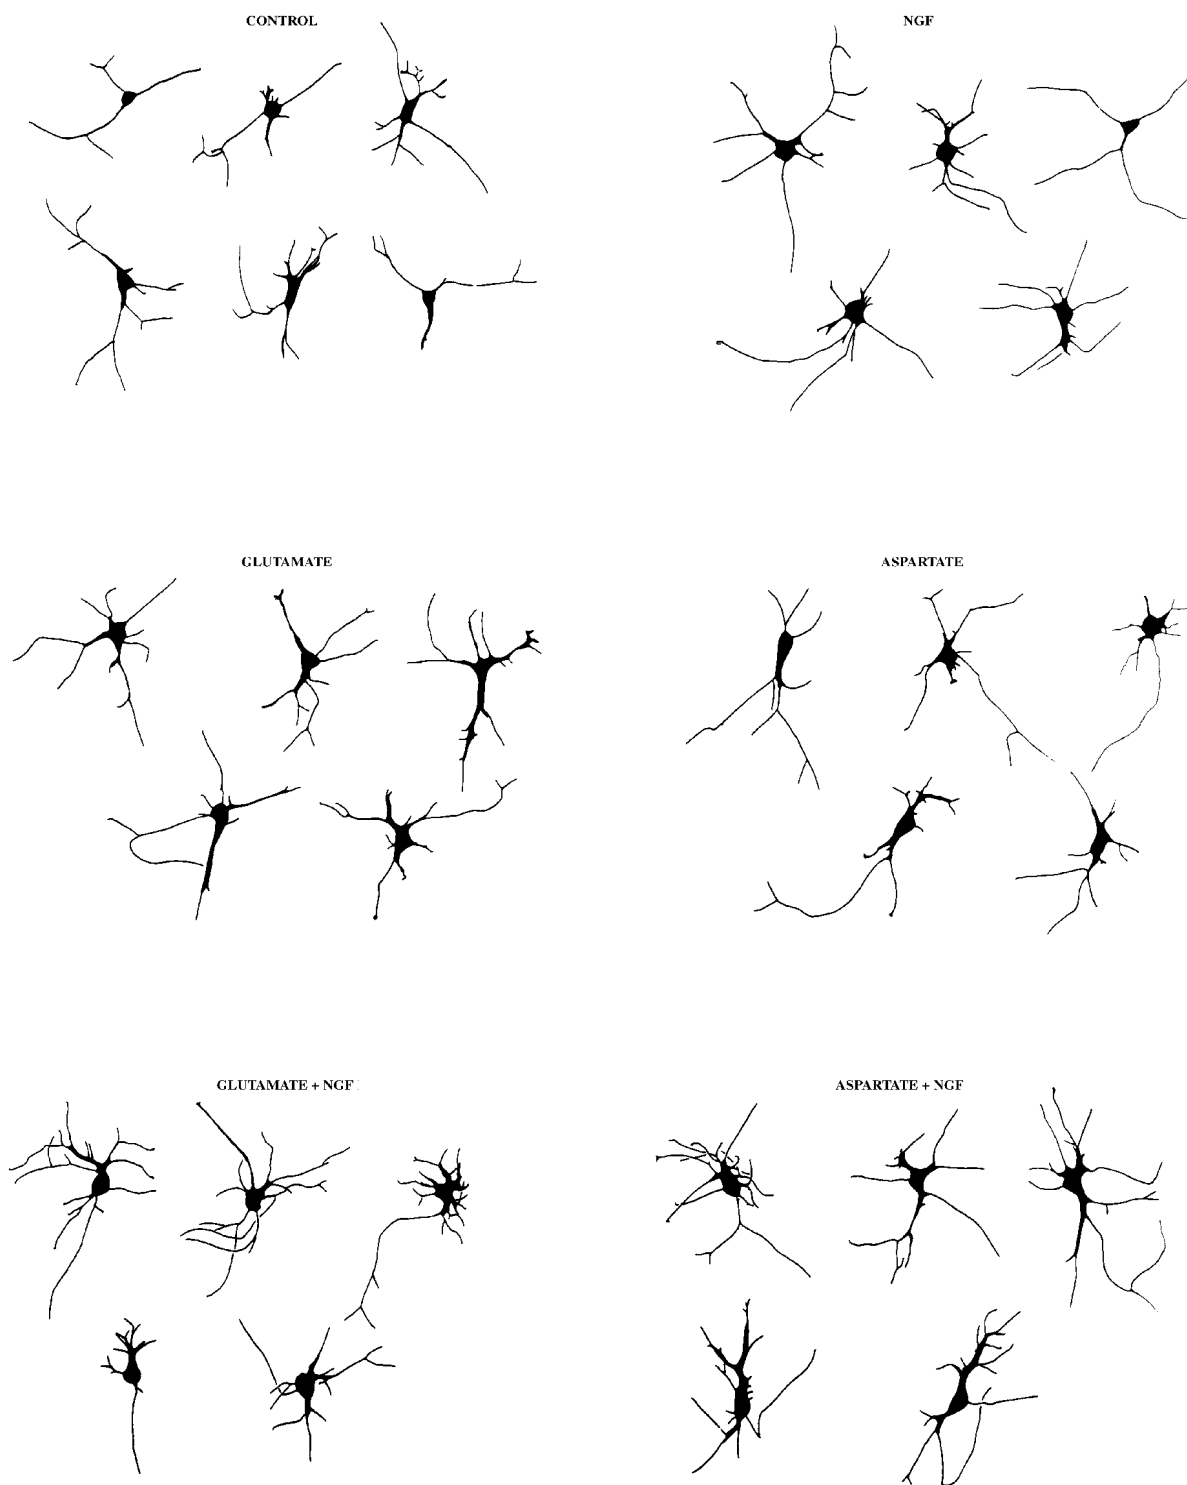

FIGURE 11.4 Morphological maturation of Purkinje cells elicited by excitatory neurotransmitters or NGF or both. Camera lucida tracings of representative CaBP-positive cells were obtained from each experimental condition. Note the marked enhancement in neurite elaboration and in cell size

after treatment with glutamate plus NGF or aspartate plus NGF. L-aspartate and L-glutamate were used at a 10- μ M final concentration, and NGF was used at 200 units/ml. Scale bar, 40 μ m. (Reprinted from Cohen-Cory, Dreyfus, and Black, 1991, by permission.)

FIGURE 11.5 Potentiation of synaptic transmission by brain-derived neurotrophic factor (BDNF). (A) Whole-cell voltage clamp recordings from a hippocampal neuron before and 3 min after exposure to BDNF ($V_{\text{hold}} = -60$ mV). (B) Effects on synaptic charge after bath application of BDNF ($n = 10$ cells), heat-inactivated BDNF ($n = 9$ cells), or nerve growth factor (NGF; $n = 13$ cells; 50 ng/ml). In some experiments, cultures

were pretreated for 1 hour with the trk tyrosine kinase inhibitor K-252a in the bath solution (200 nM; $n = 7$ cells). * $p < .001$ compared to baseline levels for that condition. Recordings were obtained from multiple platings. (Reprinted from Levine et al., 1995a, Copyright 1995 National Academy of Sciences, U.S.A.)

together, the basal forebrain–hippocampal system plays a central role in attention, learning, and memory, with a particular emphasis on spatial learning and declarative memory. In basal forebrain cholinergic neurons, NGF increases both L-type and N-type components of voltage-gated calcium currents (Levine et al., 1995b). This effect is specific to NGF, since BDNF does not have a similar effect. Calcium entry via these voltage-dependent channels regulates neurotransmitter release and neuronal firing patterns, and also modulates neuronal gene expression. Thus calcium influx via these channels may mediate some of the well-known trophic actions of NGF. Since these neurons innervate the hippocampus, this effect of NGF may also play a role in modulating hippocampal synaptic transmission.

Direct presynaptic effects of neurotrophins on transmitter release have been best characterized at the neuromuscular junction. The neuromuscular junction is a widely studied model for examining mechanisms of synaptic transmission because it is one of the most accessible and well characterized synapses in the nervous system. At developing *Xenopus* neuromuscular synapses, BDNF and NT-3 potentiate evoked synaptic currents within minutes of exposure by enhancing acetylcholine (ACh) release from presynaptic nerve terminals (Lohof, Ip, and Poo, 1993). In addition to this short-term effect, chronic exposure to BDNF or NT-3 for several days enhances synaptic maturation through effects on presynaptic processes (Wang, Xie, and Lu, 1995). Similar effects are observed in mammalian systems in vitro, where NGF and BDNF directly potentiate the release of ACh and glutamate in the hippocampus and cortex (Knipper, da Penha Berzaghi, et al., 1994). Moreover, this enhanced transmitter release appears to augment synaptic

transmission (Knipper, Leung, et al., 1994; Lessmann, Gottmann, and Heumann, 1994).

Neurotrophins also modulate synaptic activity via postsynaptic mechanisms. In the hippocampus, BDNF elicits sustained enhancement of excitatory synaptic activity within minutes of exposure (figure 11.5), leading to increased firing rate (Levine et al., 1995a). The synaptic locus of this effect was determined by making intracellular injections directly in the postsynaptic cell. In these experiments, the effect of BDNF was blocked or enhanced, respectively, by kinase or phosphatase inhibitors (figure 11.6), demonstrating that BDNF modulates postsynaptic responsiveness via phosphorylation-dependent mechanisms. Activation of the high-affinity BDNF receptor, trkB, is critical for this response, since NT-4, another trkB ligand, elicits similar effects. In contrast, the related neurotrophins, NGF and NT-3, as well as the unrelated growth factors epidermal growth factor and basic fibroblast growth factor, do not share this effect (Levine et al., 1996). A postsynaptic locus of action is substantiated by the finding that the biologically active full-length trkB receptor is an intrinsic component of the postsynaptic density (PSD), a specialization of the postsynaptic membrane that anchors neurotransmitter receptors and second-messenger-signaling molecules (Wu et al., 1996).

The postsynaptic effects of BDNF result from modulation of the NMDA subtype of glutamate receptor, which has been directly implicated in learning (Morris, Davis, and Butcher, 1990). BDNF rapidly increases neuronal responses to locally applied glutamate, the major excitatory transmitter in hippocampal circuits, but does not enhance responses to ACh (figure 11.7). Mechanisms responsible for increased

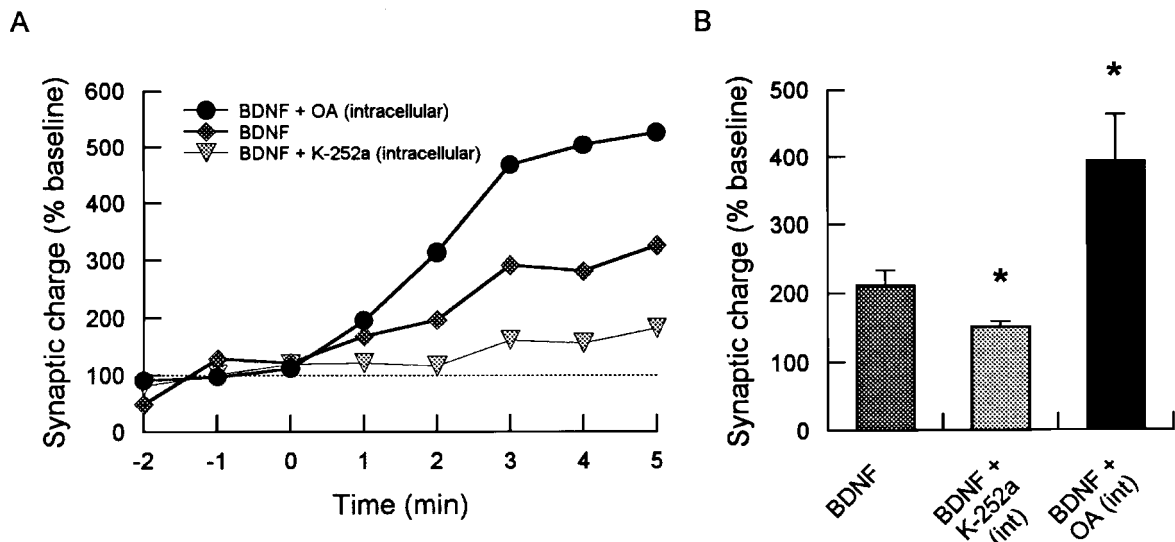

FIGURE 11.6 The effect of BDNF on synaptic charge is modified by postsynaptic manipulations. (A) Time courses of recordings from individual neurons for the effect of either bath-applied BDNF alone (50 ng/ml; diamonds), or in combination with intracellular injection of K-252a (200 nM; triangles) or okadaic acid (OA; 0.5 μ M; circles). Recordings were obtained from sister cultures. Each point represents the average synaptic

charge for a 1-minute period. (B) Effects of BDNF on synaptic charge. Intracellular injection of K-252a ($n = 8$ cells) decreased the magnitude of the charge effect compared to BDNF alone, while intracellular injection of okadaic acid ($n = 8$ cells) increased the effect. * $p < .05$. Recordings were obtained from multiple platings. (Reprinted from Levine et al., 1995a, Copyright 1995 National Academy of Sciences, U.S.A.)

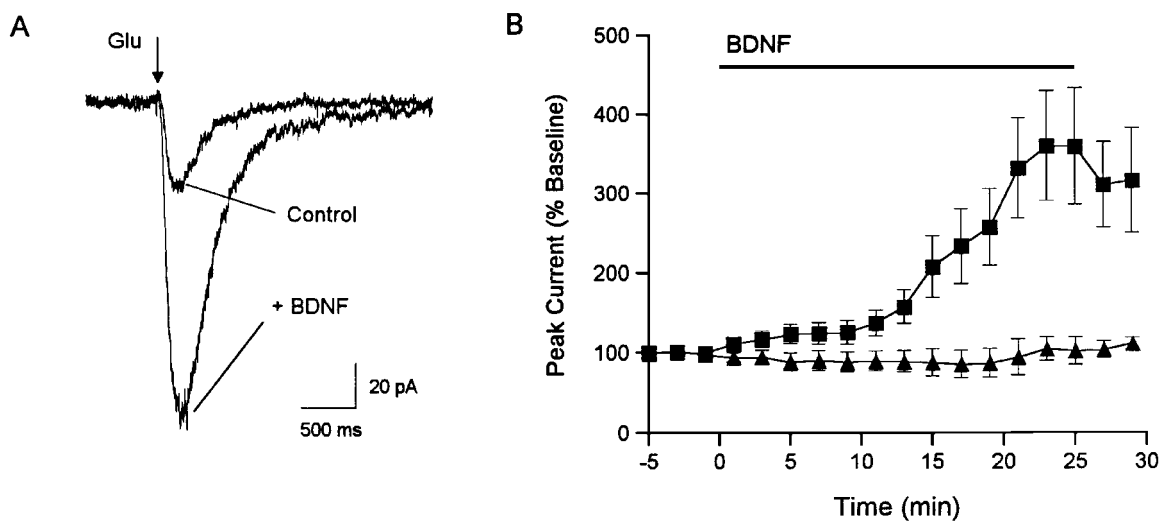

FIGURE 11.7 BDNF enhances responsiveness to iontophoretically applied glutamate but not acetylcholine. (A) Example traces of control response to glutamate iontophoresis (10-ms pulse; indicated by arrow) and response after 20 min of BDNF exposure. Holding potential was -40 mV. The iontophoresis pipette was located in the dendritic region of pyramidal cells.

Traces represent the average of five consecutive sweeps. (B) Time course of mean effect of BDNF on glutamate (squares) or acetylcholine (triangles) responsiveness (mean \pm SEM). (Reprinted from Levine et al., 1998, Copyright 1998 National Academy of Sciences, U.S.A.)

glutamate responsiveness have been revealed by monitoring the activity of individual NMDA receptor molecules with single-channel recording techniques. These recordings revealed that BDNF enhances the open probability of the NMDA receptor channel (figure 11.8), without changing channel conductance (Levine et al.,

1998). BDNF also acutely enhances phosphorylation of NMDA receptor subunits in the PSD (Suen et al., 1997; Lin et al., 1998), an effect which may underlie altered receptor function. Furthermore, modulation of NMDA receptor function plays a direct role in BDNF-induced synaptic plasticity, because this plasticity is blocked by

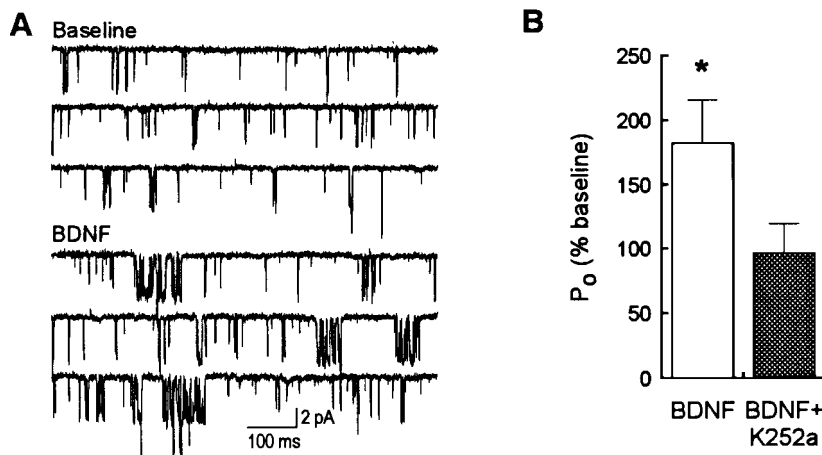

FIGURE 11.8 BDNF increases NMDA-receptor single-channel activity. (A) Example sweeps from a cell-attached single-channel recording before and during application of BDNF (20 ng/ml). This patch contained two channels. The holding potential was -80 mV. (B) Acute exposure to BDNF significantly enhanced NMDA receptor channel open probability (P_o ; $p <$

.01; $n = 9$), normalized according to the number of channels in the patch. The trk tyrosine kinase inhibitor K-252a (200 nM) completely blocked the effect of BDNF ($p > .3$; $n = 6$). (Reprinted from Levine et al., 1998, Copyright 1998 National Academy of Sciences, U.S.A.)

pharmacological antagonism of NMDA receptors (Levine et al., 1998).

Thus neurotrophins potentiate synaptic transmission via both pre- and postsynaptic effects, increasing the efficacy of synaptic transmission and the probability of triggering postsynaptic action potentials. The effects of neurotrophins on synaptic activity may have specific consequences for activity-dependent plasticity in the hippocampus, including LTP, a potential cellular substrate of learning and memory. Animals with a targeted deletion of the BDNF gene have deficits in LTP that can be restored by acute reintroduction of BDNF (Korte et al., 1995; Korte et al., 1996; Patterson et al., 1996). Endogenous BDNF also enhances LTP, although specific mechanisms are controversial (Figurov et al., 1996; Akaneya et al., 1997; Kang et al., 1997). Taken together, these data point to an important role for neurotrophins in the regulation of synaptic plasticity and, potentially, the learning and memory processes that are dependent on this plasticity.

Recent studies utilizing a hippocampal lesion model, in fact, suggest that neurotrophin-induced synaptic plasticity may play a part in learning-related changes in hippocampal function. These studies raised the possibility that hippocampal BDNF is associated with spatial memory function. Unilateral hippocampal lesions resulted in deficits in spatial learning tasks in the neonatal rat, while having far lesser effects in the adult, suggesting that the contralateral, unlesioned hippocampus is dysfunctional after neonatal lesions (Van Praag et al., 1998). This model provided the opportunity to examine neurotrophin gene expression in the remaining, apparently dysfunctional

hippocampus of rats with deranged memory function. In fact, BDNF mRNA was decreased significantly, while NGF message was unchanged, in the unlesioned hippocampus. Moreover, measures of cholinergic and GABAergic function were normal (Van Praag et al., 1998). These initial studies raise the possibility that BDNF, which regulates synaptic plasticity in vitro, also plays a role in memory mechanisms in vivo. Increasing neurotrophin availability may thus represent a novel approach toward reversing cognitive deficits resulting from injury, disease, or aging.

Some perspectives

The foregoing work provides a view of the emerging complexities of trophic roles in the brain. It is already apparent that impulse activity may influence trophic interactions at multiple loci in different cells and systems. In turn, environmental stimuli that elicit activity in any particular system may, potentially, gain access to trophic regulation and to the long-term changes that result. In principle, then, virtually instantaneous, millisecond-to-millisecond impulses may be converted into quasi-permanent neural circuit changes through distinct, definable molecular mechanisms.

Surprisingly, perhaps, these changes may be either trophic or regressive, depending on the specific EAA receptor subtypes stimulated. Potentially, then, some stimuli may increase pathway efficacy, whereas others may reduce efficacy in some systems. Relationships among experience, impulse activity, and pathway efficacy may be exceedingly complex and fine-tuned. What variables

govern the balance between metabotropic-trophic and ionotropic-regressive influences? Is the final biologic effect simply a reflection of relative expression of receptor subtype genes, or do other factors govern access of EAA to already expressed receptors? Is the expression of different receptor subtypes independently regulated at the transcriptional, translational, and posttranslational levels? Approaches to these and related questions may help elucidate the intimate relationships between survival and death, between trophism and regression. More generally, we may inquire whether the coexistent potential for both increased and decreased function is widespread, exhibited by most neuronal systems. Finally, does the trophic-regressive balance contribute to the pathogenesis of disease, and does receptor subtype specificity suggest new therapeutic approaches?

In addition to the trophic-regressive balance, studies with the hippocampal neuronal cultures imply that a balance between excitatory and inhibitory transmitters also regulates trophic factor gene expression. Consequently, experience may potentially increase or decrease pathway efficacy through excitatory or inhibitory transmitter influences. In sum, excitatory-inhibitory, trophic-regressive checks and balances may allow precise modulation of brain neural circuits.

Focusing on trophic effects alone, multiple outstanding questions demand attention. Several may be enunciated as examples to indicate future research directions. While impulse activity and specific EAA transmitters can regulate trophic-factor gene expression, are trophic genes coregulated in most systems, or does regulation occur at different levels in different systems? Since proximate glia express trophic factor in the cerebellar dissociates (Cohen-Cory et al., 1993) as well as in other brain areas in vivo and in vitro (Lu et al., 1991b), should we now envisage a trophic neuron-glia-neuron loop, in addition to the classic neuron-neuron synaptic circuit? With multiple trophic, tropic, and growth factors, in addition to the neurotrophins, how are biologic specificity and selectivity conferred; what is the balance between specificity and redundancy; which factors act sequentially on defined populations; and what are the rules of sequentiality? Are we now in a position to move from environmental stimulus to impulse activity to trophic regulation to mental function and behavior, as implied by the examples of LTP and spatial learning, cited in this chapter?

12 Stress, Sex, and the Structural and Functional Plasticity of the Hippocampus

BRUCE S. McEWEN

ABSTRACT The hippocampal formation, which expresses high levels of adrenal steroid receptors, is a plastic brain structure that is important for certain types of learning and memory. It is also vulnerable to insults such as stroke, seizures, and head trauma. The hippocampus is also sensitive and vulnerable to the effects of stress and stress hormones, and it is responsive to the actions of sex hormones as well, both during development and adult life. Stress and sex hormones regulate three types of structural plasticity in the adult hippocampus: synaptogenesis, reorganization of dendrites, and neurogenesis in the dentate gyrus.

Developmentally programmed sex differences are also seen in the hippocampus. Suppression of dentate gyrus neurogenesis and atrophy of dendrites of hippocampal pyramidal neurons are produced by chronic psychosocial stress, involving the actions of adrenal steroids acting in concert with excitatory amino acid neurotransmitters. As far as we can tell, these changes are reversible as long as stress is terminated after a number of weeks. However, there are also reports that much longer durations of psychosocial stress leads to permanent loss of hippocampal pyramidal neurons. In the human hippocampus, MRI studies along with neuropsychological testing have revealed memory impairment and atrophy of the whole human hippocampus in some individuals as they age. This is reminiscent of individual differences in aging in rodents, which appear to reflect life-long patterns of stress hormone reactivity that are developmentally programmed, although a developmental influence on human individual differences is only a matter of speculation. Hippocampal atrophy is also found in Cushing's syndrome, posttraumatic stress disorder, and recurrent depressive illness, indicating that this brain structure is vulnerable and involved in stress- and stress-hormone-related disorders. Knowledge of underlying anatomical changes and the mechanism of hippocampal atrophy may help in developing treatment strategies to either reverse or prevent them.

The brain is sensitive to hormones secreted by the adrenal cortex, gonads, and thyroid in adult life as well as in early development. The earliest evidence for the hormone responsiveness of the nervous system came from the direct implantation of steroid hormones into the brain (Barfield, 1969; Lisk, 1962). Those initial studies in the 1960s used sex hormones because reproductive be-

haviors were known to be regulated by gonadal steroids. With the introduction of tritiated steroid hormones in the 1960s, it became possible to map the location of steroid hormone receptors in brain tissue by autoradiography and in vitro binding assays (McEwen et al., 1979; Morrell and Pfaff, 1978). This mapping was based upon a model of steroid hormone action introduced in the 1960s centering on intracellular receptors that regulate genes by binding directly to DNA and are located in the cell nucleus (Jensen and Jacobson, 1962). The model of steroid action has been very influential in the current revolution in understanding regulation of gene transcription in eukaryotes (Beato and Sanchez-Pacheco, 1996; Evans, 1988; Yamamoto, 1985). This model not only provided a clear cellular target for localizing steroid receptors in brain cells but also indicated a model by which a chemical messenger could produce long-lasting effects upon neuronal structure and function.

One result of the mapping of steroid receptors was the discovery in 1968 that the hippocampal formation has receptors for adrenal steroids (McEwen, Weiss, and Schwartz, 1968). This finding, first in rats and later in primates (Gerlach et al., 1976) and birds (Rhees, Abel, and Haack, 1972), suggested that the adrenal cortex must have a far-reaching influence on this region of the brain. Indeed it does, but it has been only in the past decade that we have begun to elucidate the multiple hormonal influences in hippocampal structure and function, ranging from adaptive plasticity, which is the subject of this article, to pathophysiological changes. The hippocampal formation plays an important role in spatial and declarative memory as well as in contextual memory (Smriga, Saito, and Nishiyama, 1996). Hippocampal malfunction is implicated in schizophrenia and affective illness (Sheline et al., 1996; Axelson et al., 1993; Bogerts et al., 1993; Arnold et al., 1991; Luchins, 1990). Furthermore, glucocorticoids have a significant impact on the human hippocampus. For example, in Cushing's syndrome and after exogenous glucocorticoid therapy for inflammatory disorders, declarative memory defects have been found (Starkman et al., 1992; Newcomer et al., 1994; Wolkowitz, Reuss, and Weingartner,

BRUCE S. McEWEN Harold and Margaret Milliken Hatch Laboratory of Neuroendocrinology, Rockefeller University, New York, N.Y.

1990; Wolkowitz, Rubinow, and Doran, 1990; Martignoni et al., 1992; reviewed in Lupien and McEwen, 1997), and verbal memory scores correlated negatively with elevated cortisol and positively with MRI measures showing decreased hippocampal volume (Starkman et al., 1992). Moreover, the hippocampus is vulnerable to degenerative effects of stress and loss of neurons during aging as well as in response to ischemia, seizures, and head trauma (Hsu and Buzsaki, 1993; Lowenstein et al., 1994; Sloviter, 1994; Landfield and Eldridge, 1994; Sapolsky, 1992).

Besides responding to adrenal steroids, the hippocampus is also a target of sex hormones and thyroid hormone. Male and female rats use different strategies in spatial learning and memory, with males preferring global spatial cues, and females, local contextual information (Williams and Meck, 1991), and the hippocampus displays a number of anatomical sex differences (Gould, Westlind-Danielsson, et al., 1990; Juraska et al., 1985). Moreover, during the estrous cycle of the female rat, new excitatory spine synapses are produced and broken down (Woolley and McEwen, 1992). Developmental thyroid hormone effects have been described on learning, electrophysiology, and anatomical features of the hippocampus (Madeira et al., 1992; Crusio and Schwegler, 1991; Pavlides et al., 1991), and thyroid hormone treatment in adult life produces morphological alterations in pyramidal neurons (Gould, Allan, and McEwen, 1990).

Many of these hormone effects do not occur alone but rather in the context of ongoing neuronal activity. In

particular, excitatory amino acids and *N*-methyl-D-aspartic acid (NMDA) receptors play an important role in the functional and structural changes produced in the hippocampal formation by steroid hormones. At the same time, excitatory amino acids and NMDA receptors are involved in the destructive actions of stress and trauma on the hippocampus, and one of the challenges for future research is to understand what triggers the transition from adaptive plasticity to permanent damage. This chapter reviews the adaptive plasticity in the hippocampus produced by circulating adrenocortical, thyroid, and gonadal hormones acting in many cases in concert with excitatory amino acid neurotransmitters, and it also considers some of the ways in which adaptive plasticity gives way to permanent damage.

Salient features of hippocampal neuroanatomy

The hippocampus is organized as shown in figure 12.1, with two major regions, Ammon's horn and the dentate gyrus. The principal synaptic pathways include input to the granule cells of the dentate gyrus from the entorhinal cortex via the perforant pathway. These in turn project via the mossy fibers to the CA3 pyramidal cells, which then project via the Schaffer collaterals to the CA1 pyramidal cells.

Within the CA3 region are a number of features not shown in the diagram that have considerable significance for its functional activity and vulnerability to damage. These include the collaterals to other CA3 neurons

FIGURE 12.1 Basic neuroanatomy of the hippocampal formation, showing the three-cell circuit. This chapter describes studies showing that estrogens stimulate synaptogenesis on spines of dendrites of CA1 pyramidal neurons, whereas repeated

stress, acting via glucocorticoids, causes dendritic remodeling of CA3 pyramidal neurons. In addition, adrenal steroids participate in the regulation of neurogenesis in the adult dentate gyrus of the adult.

as well as recurrent projections from CA3 neurons lying closer to the dentate gyrus (Li et al., 1994; Ishizuka, Weber, and Amaral, 1990). Both these collateral systems contribute to the bursting pattern of CA3 neuronal activity (Li et al., 1994) that is a contributing factor to seizure-induced destruction of CA3 pyramidal neurons (Sloviter, 1994).

Besides the principal neurons, the hippocampal formation contains a variety of nonprincipal cells including the excitatory mossy cells of the dentate hilus and the inhibitory interneurons that express a variety of neurochemical features in addition to producing gamma amino butyric acid (GABA). These neurons play an important role in regulating excitability within the hippocampus (Freund and Buzsaki, 1996).

Finally, the dentate gyrus is unique within the brain in having continued neurogenesis of granule neurons during adult life (Cameron, McEwen, and Gould, 1995). The dentate gyrus is formed later than Ammon's horn, and the maturation of the dentate gyrus in the first two weeks of life in the newborn rat (Cameron and Gould, 1996) is related to the development of emotionality, as seen by the effects of neonatal handling (Meaney et al., 1988) as well as by the appearance of "behavioral inhibition" (Takahashi, 1995; Gould and Cameron, 1997). The dentate gyrus is functionally connected to the amygdala, and lesions of the basolateral amygdala impair the formation of long-term potentiation in the dentate gyrus (Ikegaya, Saito, and Abe, 1997).

Sex hormones and the hippocampus

SEX DIFFERENCES Estrogen and androgen receptors are expressed in the hippocampus of the developing and adult rat. In the developing rat brain, both estrogen receptors and aromatizing enzymes are expressed perinatally at the time of perinatal sexual differentiation and then decline to much lower levels that persist into adulthood (MacLusky et al., 1994; MacLusky et al., 1987; O'Keefe et al., 1995; O'Keefe and Handa, 1990). The cellular pattern of estrogen receptor expression is very similar in developing and adult hippocampus (S. Hayashi and C. Orikasa, personal communication).

Administration of estrogens to newborn female rats mimics the masculine sexual differentiation seen in males as far as the use of global spatial strategies in learning is concerned (Williams and Meck, 1991). Indeed, male and female rats use different strategies in spatial learning and memory, with males preferring global spatial cues, and females, local contextual information (Williams and Meck, 1991).

The hippocampus displays a number of anatomical sex differences. Notably, males have a larger dentate gyrus

and more granule neurons, and dentate gyrus volume is increased in developing female rats by neonatal androgen treatment (Roof and Havens, 1992). In addition, sex differences in the pattern of dendritic branching and the density of dendritic spines on CA3 pyramidal neurons have been reported (Gould, Westlind-Daniels, et al., 1990). Finally, environmental enrichment has different effects on hippocampal morphology in male and female rats (Juraska, Fitch, and Washburne, 1989; Juraska et al., 1985).

OVARIAN HORMONES AND SYNAPTOGENESIS Adult female rats express low levels of estrogen receptors, and these receptors are expressed in interneurons scattered throughout the hippocampus and cerebral cortex (Weiland et al., 1997). These recent studies confirm and extend earlier findings using steroid autoradiography (Loy, Gerlach, and McEwen, 1988) and immunocytochemistry (DonCarlos, Monroy, and Morrell, 1991). The newly discovered beta estrogen receptor has been reported to be expressed in CA1 and CA2 pyramidal neurons (Li, Schwartz, and Rissman, 1997), but this finding is disputed (Weiland, Alves, and Lopez, personal communication).

During the estrous cycle of the female rat, new excitatory spine synapses are produced and broken down (Woolley and McEwen, 1992; Woolley, Gould, and McEwen, 1990). This finding may help explain the variations in seizure susceptibility of the dorsal hippocampus during the estrous cycle reported in 1968 (Terasawa and Timiras, 1968), with a marked decrease in seizure threshold on the afternoon of proestrus, at the peak of estrogen and progesterone levels. Stimulated by that paper, a morphological study that demonstrated estrogen induction of dendritic spines and new synapses in the ventromedial hypothalamus of the female rat led to the discovery that the density of dendritic spines on CA1 pyramidal neurons was also increased by estradiol (Gould, Woolley, Frankfurt, et al., 1990). These effects were specific for CA1, and dendritic spine density changed cyclically during the estrous cycle of the female rat (Woolley, Gould, and McEwen, 1990). There were also parallel changes in synapse density on dendritic spines, strongly supporting the notion of synapse turnover during the natural reproductive cycle of the rat (Woolley and McEwen, 1992).

There are two particularly important features of synapse formation and breakdown. First, progesterone administration rapidly potentiated estrogen-induced spine formation but then triggered the down-regulation of spines on CA1 neurons; the progesterone antagonist RU38486 blocked the natural down-regulation of spines during the estrous cycle (Woolley and McEwen, 1993).

Second, estrogen induction of new spine synapses on CA1 pyramidal neurons is blocked by concurrent administration of NMDA receptor antagonists (Woolley and McEwen, 1994). A recent study by Woolley showed, by electrophysiological recording, dye filling, and morphometry, that estrogen treatment increases not only spine density on CA1 neurons but also currents mediated by NMDA receptors when AMPA/kainate receptors are blocked (Woolley et al., 1997).

Moreover, a prominent effect of estrogen treatment is to induce NMDA receptor binding sites in the CA1 region of the hippocampus (Gazzaley et al., 1996; Weiland, 1992a). It is therefore possible that activation of NMDA receptors themselves could lead to induction of new synapses, in which case estrogen induction of NMDA receptors would then become a primary event leading to synapse formation.

The problem with all of this plasticity in CA1 pyramidal neurons is that, as noted earlier, the only detectable intracellular estrogen receptors are found in interneurons, not in the CA1 pyramidal neurons themselves. The possible exception is the presence of the beta ER in CA1 and CA2 neurons, discussed previously. There are also no detectable estrogen-inducible intracellular progesterin receptors in hippocampus, based upon immunocytochemistry (N. G. Weiland and S. Alves, unpublished); however, there is a binding study showing low levels of such receptors in hippocampal tissue (Parsons et al., 1982). Nevertheless, recent studies with an estrogen antagonist argue strongly for a role of alpha estrogen receptors in interneurons in synapse induction. The estrogen antagonist CI-628 blocks estrogen induction of spines on CA1 neurons and does not produce any agonist effect (McEwen, Tanapat, and Weiland, 1999). This situation is reminiscent of blockade of progesterin receptor induction in hypothalamus by CI-628, which is undoubtedly an alpha estrogen receptor-mediated effect (Roy, MacLusky, and McEwen, 1979). This experiment argues against a nongenomic effect of E and is consistent with the presence of alpha, but not beta, estrogen receptors in the inhibitory interneurons (Weiland et al., 1997; McEwen, Tanapat, and Weiland, 1999).

Recent studies on embryonic hippocampal neurons in culture have revealed that estrogens induce spines on dendrites of dissociated hippocampal neurons in culture by a process that is blocked by an NMDA receptor blocker and not by an AMPA/kainate receptor blocker (Murphy and Segal, 1996). In a subsequent study, estrogen treatment was found to increase expression of phosphorylated CREB and CREB-binding protein, and a specific antisense to CREB prevented both the formation of dendritic spines and the elevation in phospho-CREB (Murphy and Segal, 1997a). In agreement with

the *in vivo* data (already discussed), estrogen receptors were located in the cultures on GAD-immunoreactive cells that constitute around 20% of neurons in the culture; estrogen treatment caused GAD content and the number of neurons expressing GAD to decrease, and mimicking this decrease with an inhibitor of GABA synthesis, mercaptopropionic acid, caused an up-regulation of dendritic spine density, mimicking the effects of estradiol (Murphy and Segal, 1997b). However, the situation in the *in vivo* hippocampus may be somewhat more complicated.

Estrogen induction of the mRNA for glutamic acid decarboxylase (GAD), a GABA synthesizing enzyme, was detected in interneurons residing within the CA1 pyramidal cell layer, a finding consistent with the known localization of estrogen receptors (Weiland, 1992b). Moreover, estrogen treatment induces GABA_A receptor binding in the CA1 region of hippocampus, an effect that may be secondary to the action on the interneurons (McCarthy et al., 1992; Schumacher, Coirini, and McEwen, 1989). However, these effects were detected a number of days after estrogen treatment and are not inconsistent with a transient repression of GAD expression, as noted earlier in discussing the cell culture studies.

Concentrating for the moment on the interneurons containing the alpha ER, it is possible that the estrogen effects on formation of synapses on CA1 pyramidal neurons are indirect and mediated through these GABA interneurons. Wong and Moss (1992) reported that two-day estradiol treatment prolongs the EPSP and increases the probability of repetitive firing in some CA1 neurons in response to Schaffer collateral (glutamatergic) stimulation. One explanation is that estrogen actions on inhibitory interneurons might in some manner disinhibit the pyramidal neurons, allowing for removal of the magnesium blockade and activation of NMDA receptors (Orchinik and McEwen, 1995). Two alternative pathways are outlined in figure 12.2. Estrogens may decrease the activity of the GABA inhibitory input to CA1 pyramidal neurons and thus disinhibit the CA1 neurons to allow for up-regulation of NMDA receptors and excitatory synapses; alternatively, estrogens may increase the activity of GABA inhibitory input to other inhibitory interneurons that synapse on CA1 pyramidal neurons, resulting in a disinhibition. As noted previously, the recent evidence from the cell culture model suggests that estrogens transiently suppress expression of glutamic acid decarboxylase in inhibitory interneurons (Murphy and Segal, 1997b), thus supporting the first model shown in figure 12.2. Neuroanatomical data on the type of GABA interneuron that expresses estrogen receptors are consistent with this notion (N. G. Weiland, unpublished).

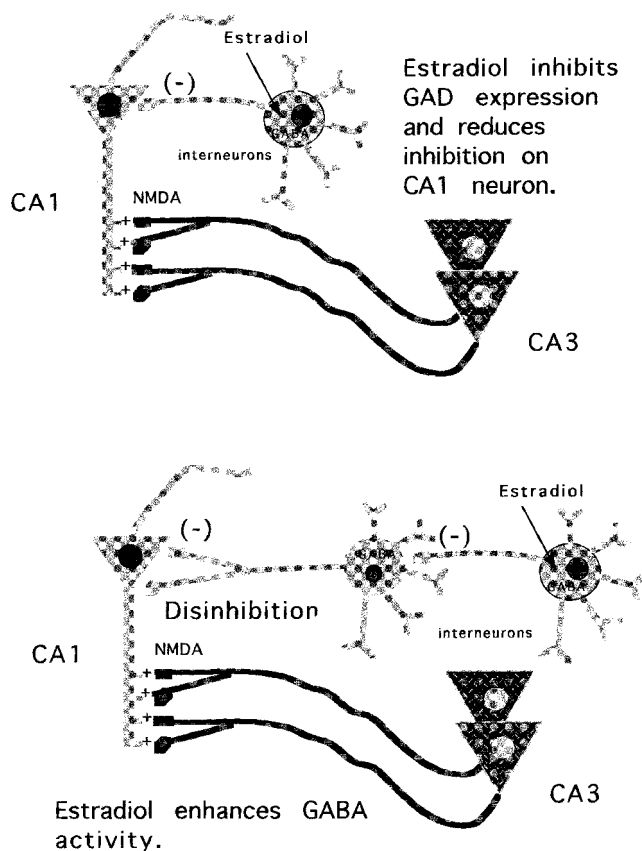

FIGURE 12.2 Alternative schemes for the role of GABA interneurons in synaptogenesis on CA1 pyramidal neurons. Estrogens may act to repress GABA activity in interneurons that synapse on CA1 neurons and produce a state of disinhibition that allows synapse formation to proceed. Alternatively, estrogens may act on GABA interneurons that synapse on other interneurons, in which case the estrogen effect might be to up-regulate GABA activity and produce a disinhibition on the CA1 pyramidal neurons.

ANDROGENS AND THE HIPPOCAMPUS The hippocampus expresses androgen receptors that are prominently localized in CA1 pyramidal neurons (J. E. Kerr et al., 1995). Androgens positively regulate androgen receptor mRNA levels in CA1, although androgen receptor binding is less sensitive to castration and hormone replacement than mRNA levels (J. E. Kerr et al., 1995).

In turn, androgen treatment induces changes in NMDA receptor expression and alters neuronal activity mediated by NMDA receptors in CA1 pyramidal neurons. Electrophysiologically, chronic treatment of castrated rats with the potent androgen dihydrotestosterone (DHT) increased the action potential duration of CA1 pyramidal neurons and decreased the amplitude of the fast hyperpolarization; moreover, DHT treatment promoted recovery of the membrane potential after depolarization with NMDA (Pouliot, Handa, and Beck,

1996). Binding of the antagonist MK801 to NMDA receptors in the CA1 region was elevated by castration, and this increase was prevented by DHT treatment, indicating that the antagonist-binding form of the NMDA receptor is affected by androgen treatment (Kus et al., 1995).

Castration increased levels of the mRNA for GnRH receptor not only on CA1 pyramidal neurons but also in the CA3 region and the dentate gyrus; curiously, however, castration decreased the second-messenger response to GnRH in hippocampal slices (Jennes et al., 1995). Except for electrophysiological studies, there is nothing to suggest a function for GnRH receptors in the hippocampus.

Androgens also have an influence on the adrenocortical response system of the hippocampus. Androgen treatment suppressed expression of Type II (glucocorticoid) receptor mRNA but had no effect on Type I (mineralocorticoid) receptor mRNA levels (J. E. Kerr, Beck, and Handa, 1996a). In this connection, castration has been reported to increase reactivity of the hypothalamo-pituitary-adrenal (HPA) axis (Handa et al., 1993). One possible reason for this effect is that castration increases reactivity of neural circuits involved in regulating HPA function. Consistent with this notion is the finding that castration increased, and androgen replacement suppressed, the immediate early gene responses to novelty in the CA1 region of the hippocampus but not in CA3 or dentate gyrus (J. E. Kerr, Beck, and Handa, 1996b).

Thyroid hormone and the hippocampus

Thyroid hormone receptors (TR) are expressed throughout the forebrain of the developing and adult rat. There are two gene products, TR alpha and TR beta, each of which has several alternately spliced variants. TR alpha 1 binds thyroid hormone, whereas the TR alpha 2 splice variant does not; TR beta 1 and TR beta 2 have identical sequences in their DNA-binding, hinge-region, and ligand-binding domains and differ only at the amino terminal region as a result either of alternative splicing or alternative promotor usage (Lechan et al., 1993). In adult life, TR alpha 1 and TR alpha 2 mRNA are expressed at similar levels in olfactory bulb, hippocampus, and granular layer of the cerebellar cortex, whereas TR beta mRNAs were concentrated in the anterior pituitary and parvocellular paraventricular nucleus (Bradley, Young, and Weinberger, 1989). A related mRNA, REV-ErbA alpha, which fails to bind thyroid hormone, was concentrated in the cerebral cortex (Bradley, Towle, and Young, 1992; Bradley, Young, and Weinberger, 1989). In contrast to the mRNA, immunoreactivity for the TR beta 2

protein was expressed in cerebral cortex, cerebellum, and hypothalamus in areas where the mRNA had not been identified (Lechan et al., 1993). Likewise, TR beta 1 immunoreactivity was found widely expressed in the forebrain, with highest levels in cerebral cortex, particularly parietal cerebral cortex layer 1, olfactory bulb, and hippocampus; thyroidectomy resulted in increased immunoreactivity in a number of brain regions, particularly in habenula and the CA3 region of the hippocampus (Nobrega et al., 1997).

In the developing brain, TR beta 2, which binds to adult anterior pituitary, is expressed in developing hippocampus and striatum, whereas TR alpha 1 and TR alpha 2 mRNAs are expressed in the fetal neocortical plate where there is active neurogenesis (Bradley, Towle, and Young, 1992). Hyperthyroidism early in neonatal life alters hippocampal morphology and the neurochemistry and structure of the basal forebrain cholinergic system of rats (Gould, Woolley, and McEwen, 1991; Westlind-Danielsson, Gould, and McEwen, 1991). In spite of these effects, sex differences in these systems persist in both basal forebrain and hippocampus (Gould, Westlind-Danielsson, et al., 1990; Westlind-Danielsson, Gould, and McEwen, 1991). The same was true for morphological changes in the dendrites of CA3 pyramidal neurons: Hyperthyroid animals had more thorny excrescences in stratum lucidum and longer and more extensively branched apical dendrites (Gould, Westlind-Danielsson, et al., 1990). Astroglial cells in the basal forebrain and septal area were also larger and more extensively branched (Gould, Frankfurt, et al., 1990).

But this hypertrophy is not necessarily to the benefit of the treated animal. On one hand, in the rat experiments cited earlier, both male and female hyperthyroid animals are slower to acquire a hippocampal-dependent spatial learning task and are somewhat impaired in showing long-term potentiation in the hippocampus (Pavlidis et al., 1991). On the other hand, a strain of mice that normally shows poor spatial learning and may have a congenital deficiency of thyroid hormone secretion during early development displays a beneficial effect of the same kind of neonatal thyroid hormone treatment (Schwegler et al., 1991). Thus there is an optimal level of thyroid hormone that is associated with optimal cognitive performance, and deviations in the direction of both hyper- and hypothyroidism result in deficiencies in neural development and cognitive function.

A hyperthyroid state in adult life, induced by repeated thyroid hormone treatment, produced morphological alterations in hippocampal pyramidal neurons, involving a reduction in spine density (Gould, Allan, and McEwen, 1990), which is different from and opposite to the effects described for hyperthyroidism in the neonatal

rat brain. Like sexual differentiation, described earlier, this is one more example of how the effects of hormones change as the brain matures.

Changes in response to thyroid hormones have been studied in hippocampus as a function of developmental age. In the CA3 region, the main effect of hypothyroidism involved decreases in volume of the pyramidal cell layer and increases in packing density of pyramidal neurons without reductions in neuronal number (Madeira et al., 1992). These effects were evident whether the hypothyroid condition was during the first 30 days of neonatal life, or between 30 and 180 days, or for the entire 180-day period (Madeira et al., 1992). In the CA1 region, however, there was evidence of neuronal loss (Madeira et al., 1992).

Adrenal steroids and the hippocampus

RECEPTORS AND EFFECTS The two types of receptors for adrenal steroids in hippocampus are the Type I or mineralocorticoid receptors (MR), and the Type II or glucocorticoid receptors (GR). It is evident from the distribution of mRNA and binding for Type I and Type II adrenal steroid receptor subtypes that neurons in dentate gyrus and Ammon's horn most likely contain both types of receptors (Herman et al., 1989), and indeed this fact has been demonstrated (see DeKloet et al., 1998). Several variants of MR and GR have been demonstrated: for MR, these are located in the untranslated region and may affect regulation of receptor expression (Kwak et al., 1993); for GR, there are receptor variants of the untranslated region, as well as some receptor variants that differ in the translated part of the mRNA (Bamberger et al., 1997; Bamberger, Schuller, and Chrousos, 1996). Another potentially important variable is that MR and GR can form heterodimers, and this activity is likely to affect the nature of the transcriptional regulation that these receptors exert (Trapp and Holsboer, 1996). MR and GR homodimers bind to the same glucocorticoid response elements (GRE) in transfection systems (Arriza et al., 1988), but they have different interactions with proteins coassociated with the receptors (Pearce and Yamamoto, 1993). In the brain and immune system, in cells that express both receptor types, MR and GR show some cross talk with each other as far as regulating their own expression: The primary direction of this effect is for MR occupancy to reduce GR expression at the mRNA (Chao, Ma, et al., 1998) and binding (Miller et al., 1993; Luttge, Rupp, and Davda, 1989) levels.

There are a number of effects mediated by MR and GR in the hippocampus and other brain regions, and most of them reflect unique actions of either MR or GR; see table 12.1. Type II receptors, which are present in the

TABLE 12.1
Neurotransmission

Neurochemical	Brain Region	Receptor Type	Reference
Neuropeptide Y	Hippocampus, hilus	Type I	Watanabe, Akabayashi, and McEwen, 1995
Dynorphin	Hippocampus, DG	Type I	Watanabe, Weiland, and McEwen, 1995
Kainate receptors	Hippocampus, DG	Type I	Watanabe, Weiland, and McEwen, 1995
Vasopressin V1 receptors	Hippocampus	Type I	Saito et al., 1996
Oxytocin receptors	Hippocampus	Type I	Liberzon et al., 1994; Liberzon and Young, 1997
5-HT1A receptors	Hippocampus, DG, CA3	Type I	Kuroda et al., 1994
5-HT2 receptors	Cerebral cortex	Type II	Kuroda et al., 1993
Corticotrophin releasing factor	Hypothalamus, PVN	Type II	Albeck, Hastings, and McEwen, 1994
Neurokinin A (Substance P)	Caudate, bed nucleus	Type I & Type II	Pompei, Riftina, and McEwen, 1995

paraventricular nuclei of the hypothalamus, mediate a profound suppression of CRH mRNA, whereas stimulating the Type I receptor had no effect (Albeck et al., 1997). Both MR and GR mediate increased levels of neurokinin A mRNA in the caudate and bed nucleus of the stria terminalis (Pompei, Riftina, and McEwen, 1995). In contrast to these results, MR activation in the hippocampus is responsible for a number of effects of adrenal steroids on neurochemical features of this brain region, including increased expression of dynorphin mRNA and kainate receptors in the dentate gyrus, increased expression of oxytocin and vasopressin receptors in hippocampus, and repression of neuropeptide Y expression in the dentate hilus as well as repression of 5-HT1A receptor expression in the dentate gyrus and CA3 region (see table 12.1).

Adrenal steroids influence the levels of mRNAs for a number of neurotrophins and do so via the two different receptors. Adrenalectomy increases the expression of BDNF mRNA in CA1 and CA3 regions of the hippocampus and decreases the expression of NT3 and basic FGF mRNA in the CA2 region (Chao, Sakai, et al., 1998). Type I receptor activation reverses the ADX effect and increases expression of basic FGF mRNA and NT3 expression in the CA2 region of the hippocampus, whereas the combination of Type I and Type II receptor activation is most effective in reversing the effect of ADX on BDNF mRNA levels (Chao, Sakai, et al., 1998). The mRNA for a key growth cone and structural marker, GAP43, is increased by ADX, and this effect is reversed by the combination of Type I and Type II receptor activation (Chao, Sakai, et al., 1998), although previous work suggested that this was mainly a Type I receptor effect (Chao and McEwen, 1994).

Type II receptors are not entirely without effects in the hippocampus. Type II receptor activation suppresses neurogenesis in the developing, but not adult, rat dentate gyrus (see the next subsection), and Type II receptors mediate the excitotoxin-induced damage to hip-

pocampal neurons in culture (Packan and Sapolsky, 1990). Type II receptors also mediate inhibitory effects on long-term potentiation in the hippocampus and promote long-term depression (see the next subsection). In general, Type II receptors oppose the actions mediated by Type I receptors on a number of markers of excitability and neurotransmission in the hippocampus (DeKloet et al., 1998).

The findings of distinctly different effects mediated by Type I and Type II receptors have implications for the genomic mechanisms by which these receptors produce their effects on gene transcription. Clearly, the classical GRE, with which both Type I and Type II receptors interact to regulated gene transcription (Arriza et al., 1988), is not a sufficient explanation for the separate actions of these two receptor types on hippocampal processes. Alternative mechanisms involve the differential ability of Type II receptors to interact with fos-jun heterodimers and other proteins (Beato and Sanchez-Pacheco, 1996) as well as the formation of MR-GR heterodimers (Trapp and Holsboer, 1996). See also DeKloet and colleagues (1998) for discussion of this topic.

STRESS, ADRENAL STEROIDS, AND NEURONAL EXCITABILITY A single burst of high-frequency stimulation to hippocampal afferents can immediately alter the responsiveness of neurons to further stimuli, an effect lasting over a time course of many hours to days. This type of plasticity is called long-term potentiation (LTP) (Bliss and Lomo, 1973). An *in vivo* study demonstrated in the hippocampal CA1 field that acute stress suppressed LTP (Diamond, Fleshner, and Rose, 1994). An acute injection of glucocorticoids produced an inhibition of LTP in the dentate gyrus (Pavlidis, Watanabe, and McEwen, 1993). With regard to glucocorticoid levels, an inverted U-shaped curve was found with regard to induction of plasticity in the CA1 field in relation to circulating corticosterone (CORT) levels; that is, both adrenocortical insufficiency as well as high levels of CORT had a detrimental effect

on potentiation, whereas optimal potentiation was obtained within an intermediate range (10–20 µg/dl) of circulating CORT (Diamond et al., 1992).

More recent studies have begun to dissect the underlying mechanism and the role of Type I and Type II receptors. Within the dentate gyrus, LTP can be modulated biphasically by adrenal steroids acting via Type I and Type II receptors; LTP was found to be enhanced within an hour by adrenal steroids acting via Type I receptors, whereas Type II receptor stimulation was found to rapidly suppress LTP (Pavlidis, Watanabe, et al., 1995). The enhancement by Type I receptor stimulation lasted for more than 24 hours in awake freely moving animals, whereas LTP disappeared in a few hours in the dentate gyrus of adrenalectomized rats without steroid replacement (Pavlidis et al., 1994). The CA1 field responded to corticosteroids in a biphasic manner similar to that of the dentate gyrus (Pavlidis et al., 1996); and the same was true of the commissural/associational input to CA3 but not for the mossy fiber input (C. Pavlidis and B. McEwen, unpublished). These biphasic effects may help to explain the inverted U-shaped dose response curve with respect to induction of LTP in the CA1 region of Ammon's horn, noted previously (Diamond et al., 1992).

One of the unexpected effects of adrenal steroid receptor stimulation was the finding that, in adrenalectomized rats, Type II receptor activation facilitated the expression of long-term depression (LTD), which is elicited by low-frequency stimulation of afferents to dentate gyrus (Pavlidis, Kimura, et al., 1995). Though first demonstrated in dentate gyrus, this effect was recently demonstrated in CA1 and was shown to be mimicked by stress and to involve a transcriptional mechanism (Xu et al., 1998).

It is important to note that the mossy fiber input to the CA3 lacked any facilitation via Type I receptor activation or any inhibition via Type II receptors; instead, Type II receptor stimulation actually facilitated the population spike of LTP after mossy fiber stimulation (Pavlidis and McEwen, in press). Because mossy fiber LTP is independent of NMDA receptors (Weisskopf, Zalusky, and Nicoll, 1993; Derrick, Weinberger, and Martinez, 1991) whereas the other forms of LTP involve NMDA receptors, it appears that the biphasic modulation of LTP may involve modulation of NMDA receptors. In this connection, adrenal steroids and stress have been reported to regulate expression of NMDA receptors in the hippocampus (Gottesman, 1997; Bartanusz et al., 1995) and other brain regions (Fitzgerald et al., 1996; Shors et al., 1997).

The precise mechanisms underlying the stress-induced impairments in LTP are not yet established.

While CORT may be modulating LTP directly, via its action on hippocampal cells, the endogenous opiates and neurotransmitters like glutamate and serotonin may also be involved. Tail shock in a restraining tube for 30 minutes caused hippocampal slices from these rats to show significantly less LTP in CA1 pyramidal neurons (Foy et al., 1987). Although LTP was affected, paired-pulse facilitation was not altered, indicating that inhibitory mechanisms were not affected (Shors, Weiss, and Thompson, 1992). Adrenalectomy blocked the stress effect, but this effect was related to the adrenal medulla, since corticosterone did not restore the effect whereas adrenal demedullation mimicked the effect of total adrenalectomy (Shors, Levine, and Thompson, 1990). Moreover, naltrexone, an opiate antagonist, also blocked the effect of stress, suggesting that an endogenous opioid mechanism may be involved (Shors, Seymour, and Thompson, 1990). The inhibitory effects of environmental stressors were found in other paradigms. An inhibitory effect on LTP was found after one week of training to escape low-intensity foot shock in a shuttle box and was more evident in the yoked control, which could not escape the shock (Shors et al., 1989). In another study, exposure of rats to a novel environment resulted in a rapid and reversible impairment of plasticity *in vivo* in the CA1 region (Diamond, Fleshner, and Rose, 1994).

Recent studies have reported that plasticity in the hippocampus is accompanied by induction of a number of immediate early genes (IEGs; Abraham, Dragunow, and Tate, 1991; Worley et al., 1993). In the hippocampus of unanesthetized, freely behaving animals, it has been shown that IEGs including the *fos* and *jun* families, *zif/268*, and *krox*, to name but a few, are activated following the induction of LTP. Interestingly, *fos* and *zif/268* have also been shown to increase in a number of brain areas, including the hippocampus, following acute stress (Melia et al., 1994; Watanabe, Stone, and McEwen, 1994; Schreiber et al., 1991). Activation of these IEGs in turn may regulate the expression of various late effector genes, for example, *F1/GAP-43*, which could then produce structural changes that would be required for the long-term maintenance of plasticity. Because steroid hormone receptors are known to interact with immediate early genes via "composite response elements" on target genes (Miner and Yamamoto, 1991), it is conceivable that the actions of aldosterone to facilitate LTP (Pavlidis et al., 1996; Pavlidis, Watanabe, et al., 1995; Pavlidis et al., 1994) are accompanied by an increased expression of genes that participate in the establishment of new structural connections. Future studies must explore the structural and neurochemical changes that accompany the steroid enhancement of LTP, including

possible interactions between glucocorticoids and induction of IEGs, and changes in structural protein and neurotrophin gene expression.

REGULATION OF DENTATE GYRUS NEUROGENESIS AND NEURONAL REPLACEMENT Granule neurons of the adult dentate gyrus depend on adrenal steroids for their survival. This dependence can be seen by the fact that adrenalectomy (ADX) of an adult rat causes increased granule neuron death (Gould, Woolley, and McEwen, 1990; Sloviter et al., 1989). However, neuronal death is only one part of the story because continuous birth of granule neurons occurs in the adult dentate gyrus, and neurogenesis also increases following ADX (Cameron and Gould, 1994).

The first clue as to the magnitude of the ADX effect on neuronal death in dentate gyrus was the finding that, three months after ADX of adult rats, some rats showed almost total loss of dentate gyrus granule neurons (Sloviter et al., 1989). This finding attracted considerable attention because it conflicted with the prevalent view of stress- and glucocorticoid-induced neuronal death in Ammon's horn (see below); it was also very puzzling because only some ADX rats showed the loss of the entire dentate gyrus.

We now have more information that allows us to understand these events better, based on the unique nature of adrenal steroid actions in dentate gyrus. ADX has been shown to induce apoptotic death of dentate granule neurons within 3–7 days in virtually every rat from which all adrenal tissue has been removed (Gould, Woolley, and McEwen, 1990). Loss of the entire dentate gyrus only in some rats may well be explained by absence of accessory adrenal tissue in those rats; when not removed at the time of ADX, this tissue can supply enough adrenal steroids to prevent neuronal loss.

In adult rats, very low levels of adrenal steroids, sufficient to occupy Type I adrenal steroid receptors, completely block dentate gyrus neuronal loss (Woolley et al., 1991). Curiously, however, in newborn rats Type II receptor agonists protect against neuronal apoptosis (Gould, Tanapat, and McEwen, 1997). This finding is consistent with the fact that dentate neuronal loss in the developing rat occurs at much higher circulating steroid levels than in the adult, and it represents another example of the different ways that the two adrenal steroid receptor types are involved in hippocampal function.

It should be noted that granule cell birth is also accelerated by ADX, and that the newly born neurons in the adult dentate gyrus arise in the hilus, very close to the granule cell layer, and then migrate into the granule cell layer, presumably along a vimentin-staining radial glial network that is also enhanced by ADX (Cameron et al.,

1993). Specific antibodies to neuron-specific enolase (NSE) have been used to show that the majority of newly born cells in the adult dentate gyrus are neurons. Using this approach, neurogenesis has been recognized in the adult rat, mouse, tree shrew, and marmoset dentate gyrus (Kempermann, Kuhn, and Gage, 1997; Gould et al., 1998; Gould, McEwen, et al., 1997; Cameron, McEwen, and Gould, 1995), strongly suggesting that this form of plasticity also operates in the adult brain.

In spite of the previously mentioned role for Type I adrenal steroid receptors in suppressing neuronal turnover in adult dentate gyrus, it should be noted that most neuroblasts labeled with [³H] thymidine lack both Type I and Type II adrenal steroid receptors (Cameron et al., 1993) as well as NMDA receptors (Pennartz and Kitai, 1991), indicating that steroidal regulation occurs via messengers from an unidentified steroid-sensitive cell. The possibility that other trophic factors may be involved is currently under investigation. Recent evidence suggests that the EGF receptor may play an important role in the signaling of stem cells to begin division and differentiation into granule neurons (Tanapat and Gould, 1997).

Besides adrenal steroids, excitatory amino acids acting via NMDA receptors regulate neurogenesis in the dentate gyrus (Cameron, McEwen, and Gould, 1995). Blockade of NMDA receptors in an adult rat with a single dose of an antagonist increased neuron number by 20% over a number of weeks; lesions of the entorhinal cortex input to the dentate gyrus also increased neurogenesis (Cameron, McEwen, and Gould, 1995). The increase in neurogenesis is not accompanied by a measurable change in apoptosis. Figure 12.3 summarizes the dual regulation of neuronal turnover by adrenal steroids and excitatory amino acids.

One explanation for why the dentate gyrus makes new cells in adult life, as well as gets rid of them, is that it does so in order to process spatial information and related aspects of memory (Sherry, Jacobs, and Gaulin, 1992). Birds that use space around them to hide and locate food, as well as voles and deer mice that traverse large distances to find mates, have larger hippocampal volumes than closely related species that do not; moreover, there are indications that hippocampal volume may change during the breeding season (Galea et al., 1994; Sherry, Jacobs, and Gaulin, 1992). It remains to be determined whether it is the dentate gyrus that exhibits this plasticity. One clue is that the rate of neurogenesis in the male and female prairie vole varies according to the breeding season (Galea, Tanapat, and Gould, 1996). Moreover, an enriched environment has been found to increase dentate gyrus volume in mice by increasing neuronal survival without altering the rate of

FIGURE 12.3 Regulation of neurogenesis and neuronal turnover in the dentate gyrus by excitatory amino acids acting via NMDA receptors and by adrenal steroids. Adrenalectomy in-

creases both neurogenesis and neuronal apoptosis, whereas the main effect of blocking NMDA receptors or lesioning excitatory input from entorhinal cortex is to increase neurogenesis.

neurogenesis (Kempermann, Kuhn, and Gage, 1997). This finding illustrates in another way the balance between neuronal apoptosis and neurogenesis.

Another aspect of this balance concerns the effects of acute and chronic stress. Acute stress involving the odor of a natural predator, the fox, inhibits neurogenesis in the adult rat (Galea, Tanapat, and Gould, 1996). Acute psychosocial stress in the adult tree shrew, involving largely visual cues, inhibits neurogenesis (Gould et al., 1997). Inhibition of neurogenesis is also seen in the dentate gyrus of the marmoset after acute psychosocial

stress (Gould et al., 1998). Chronic psychosocial stress in the tree shrew results in a more substantial inhibition of neurogenesis than after a single acute stressful encounter; moreover, the dentate gyrus is 30% smaller in the chronically stressed tree shrew, although granule neuron number only shows a trend for reduction (Fuchs et al., 1997). This finding suggests that there may be other changes such as atrophy of dendritic branching to account for the decrease in dentate gyrus volume.

Finally, what are the consequences for hippocampal function of altering dentate gyrus volume and the rates

of neurogenesis and neuronal apoptosis? In the enriched environment studies (Kempermann, Kuhn, and Gage, 1997), increased dentate gyrus volume was accompanied by better performance on spatial learning tasks. In contrast, chronically stressed tree shrews display impaired spatial learning and memory (Gould et al., 1997), although this impairment might be as much due to atrophy of dendrites of CA3 pyramidal neurons (see the next subsection) as to reduced dentate gyrus neurogenesis (see previous paragraph). Regarding the effects of long-term ADX, several reports have indicated that rats that have substantial granule neuron loss in the dentate gyrus (Sloviter et al., 1989) show modest deficits in spatial memory (Vaher et al., 1994; Conrad and Roy, 1993; Armstrong et al., 1993).

STRESS, ADRENAL STEROIDS, AND NEURONAL ATROPHY Aus der Muhlen and Ockenfels reported in 1969 that ACTH or cortisone administration to mature guinea pigs caused neurons in hippocampus and other forebrain regions to stain darkly and appear necrotic, as if undergoing atrophy. A similar finding was reported recently for tree shrews undergoing chronic psychosocial stress (Fuchs, Uno, and Flugge, 1995) in which there is also evidence for dendritic atrophy (Magarinos et al., 1996) as well as inhibition of dentate gyrus neurogenesis (see the preceding subsection). While the interpretation of these findings may be questioned in light of more recent findings regarding artifacts that can develop in fixing brains for histological analysis (Cammermeyer, 1978), the findings of aus der Muhlen and Ockenfels were instrumental in stimulating the work of Landfield and colleagues showing that aging in the rat results in some pyramidal neuron loss in hippocampus and that this loss is retarded by adrenalectomy in midlife (for review, see Landfield, 1987).

Robert Sapolsky then demonstrated that 12 weeks of daily CORT injections into young adult rats mimicked the pyramidal neuron loss seen in aging (Sapolsky, Krey, and McEwen, 1985). He went on to demonstrate that excitatory amino acids play an important role in the cell loss by showing, first, that CORT exacerbates kainic acid-induced damage to hippocampus, as well as ischemic damage and, second, that glucocorticoids potentiate excitatory amino acid killing of hippocampal neurons in culture (for review, see Sapolsky, 1992).

In order to examine what actually happens to hippocampal neurons over a shorter time period as a result of glucocorticoid exposure or repeated stress, we used the single-section Golgi technique to demonstrate that, after 21 days of daily corticosterone exposure, the apical dendritic tree of CA3 pyramidal neurons has undergone atrophy (Woolley, Gould, Frankfurt, et al., 1990). A similar

atrophy was also produced by 21 days of repeated restraint stress in rats (Watanabe, Gould, and McEwen, 1992) and by 28 days of daily psychosocial stress in tree shrews (Magarinos et al., 1996). In a psychosocial stress model in rats, both dominant and subordinate animals show dendritic atrophy of CA3 pyramidal neurons within 14 days (McKittrick et al., 1996).

Dendritic atrophy caused by corticosterone exposure and by restraint or psychosocial stress was prevented by the daily administration of the antiepileptic drug phenytoin prior to stress or corticosterone treatment (Magarinos et al., 1996; Watanabe, Gould, Cameron, et al., 1992). This finding indicates that neural activity and the release and actions of excitatory amino acids are involved, since phenytoin blocks glutamate release and antagonizes sodium channels and t-type calcium channels that are activated during glutamate induced excitation (see Magarinos et al., 1996; Watanabe, Gould, Cameron, et al., 1992). Subsequent work revealed that NMDA receptor blockade is also effective in preventing stress-induced dendritic atrophy (Magarinos and McEwen, 1995). Thus glucocorticoid treatment can cause atrophy, but, because corticosteroids are released during stress in lower amounts than that which is given exogenously to cause atrophy (Watanabe, Gould, and McEwen, 1992), it was important to determine whether glucocorticoids play a role in stress-induced atrophy.

We used the steroid synthesis inhibitor cyanoketone to reduce the magnitude of corticosterone secretion in response to restraint stress (Magarinos and McEwen, 1995). Cyanoketone attenuates the adrenal steroid stress response but allows basal secretion to occur (Akana et al., 1988). We found that cyanoketone treatment blocked the atrophy of dendrites induced by daily restraint stress (Magarinos and McEwen, 1995).

Several links exist between glucocorticoids and excitatory amino acids. First, excitatory amino acid release is affected by adrenalectomy, which markedly reduces the magnitude of the EAA release evoked by restraint stress (Moghaddam et al., 1994; Lowy, Gault, and Yamamoto, 1993). Second, stress and glucocorticoids increase expression of NMDA receptors or the mRNAs for their subunits (Weiland, Orchinik, and Tanapat, 1997). Finally, adrenal steroids regulate expression of the presynaptic kainate autoreceptor on mossy fiber terminals (Watanabe, Weiland, and McEwen, 1995; Joels et al., 1996), an effect that may enhance the positive feedback of glutamate release upon itself (Chittajallu et al., 1996).

Repeated restraint stress for 21 days causes a suppression of 5-HT_{1A} receptor binding in the dentate gyrus and CA3 region of the hippocampus (Mendelson and

FIGURE 12.4 Repeated stress acts via adrenal steroids and NMDA receptors to cause dendrites to atrophy and reorganize on the apical side of CA3 pyramidal neurons. Blocking glucocorticoid synthesis inhibits this process; likewise blocking NMDA receptors or interfering with excitatory neurotransmission with Dilantin prevents stress-induced dendritic atrophy. Finally, treatment of rats undergoing stress with a benzodiaz-

epine, adinazolam, or with a serotonin reuptake enhancer, tianeptine, prevents stress-induced dendritic remodeling. The benzodiazepine is presumed to act to enhance inhibitory input to CA3 neurons, whereas the speculative role of tianeptine may be to reduce the effect of extrasynaptic 5-HT to increase NMDA receptor activity.

McEwen, 1992), and psychosocial stress depresses 5-HT transporter expression as well as 5-HT_{1A} receptor binding in these hippocampal subregions (McKittrick et al., 1995, 1996). Because serotonin is released by stressors (Kennet, Dickinson, and Curzon, 1985) and may play a role in the actions of stress on nerve cells, we investigated the actions of agents that facilitate or inhibit serotonin reuptake. Tianeptine is known to enhance serotonin uptake (Whitton et al., 1991; Mennini, Mocaer, and Carattini, 1987), and we compared it with fluoxetine, an inhibitor of 5-HT reuptake (Beasley, Masica, and Potvin, 1992), as well as with desipramine as an inhibitor of noradrenaline uptake. Only tianeptine was effective in preventing atrophy (Watanabe, Gould, Daniels, et al., 1992; Magarinos, Deslandes, and McEwen, in press). Tianeptine also blocked glucocorticoid-induced atrophy of CA3 dendrites (Watanabe, Gould, Daniels, et al., 1992), indicating that this effect is not a result of any interference with glucocorticoid secretion. There is a connection between 5-HT and excitatory amino acids, including evidence of interactions between serotonin and NMDA receptors indicating that serotonin potentiates NMDA receptor binding as well as activity of NMDA receptors and may do so via 5-HT₂ receptors (Rahmann and Neumann, 1993; Mennini and Miari, 1991).

Inhibitory interneurons play a major role in regulating excitability of the hippocampus. Indeed, treatment with a benzodiazepine agonist, adinazolam, effectively blocks stress-induced atrophy of CA3 apical dendrites (Magarinos and McEwen, submitted). Figure 12.4 summarizes the present state of knowledge about the multiple control of dendritic atrophy in the CA3 region of the hippocampus.

The interneurons that receive intense innervation from mossy fibers of dentate gyrus granule neurons are especially vulnerable to a variety of insults (Hsu and Buzsaki, 1993). If some of these neurons were to die as a result of repeated restraint stress, then there might be a cumulative effect over time, in which repeated bouts of stress might progressively deplete the dentate gyrus of the buffering action that these inhibitory neurons appear to provide. However, this statement may apply to much longer intervals of repeated stress, because the dendritic atrophy described thus far is reversible.

Stress-induced atrophy of dendrites is reversible within 7–10 days of the termination of stress (C. Conrad, A. Magarinos, J. Ledoux, B. S. McEwen, unpublished); and this stands in contrast to the irreversible damage and neuron loss that have been attributed to head trauma, stroke, seizures, and severe long-term stress (discussed earlier). This reversibility is reminiscent of stud-

ies of hippocampal morphology in hibernating animals. Hibernation causes dendritic retraction of CA3 pyramidal neurons in ground squirrels, whereas bringing squirrels out of the hibernating state results in rapid dendrite expansion (Popov and Bocharova, 1992; Popov, Bocharova, and Bragin, 1992). A similar finding was made for hibernating European hamsters (A. Magarinos, B. S. McEwen, and P. Pevet, unpublished). Therefore, with regard to underlying mechanisms, we are drawn toward reversible plasticity and growth processes in the dendritic tree, as will be discussed in the next subsection.

STRESS-INDUCED SYNAPTIC VESICLE REORGANIZATION WITHIN MOSSY FIBER TERMINALS Recent electron microscope studies have provided new insights into the relationship between excitatory amino acids and glucocorticoids and a new morphological end point of repeated stress (Magarinos, Verdugo Garcia, and McEwen, 1997). Because the mossy fibers from dentate granule neurons provide a major excitatory input to the CA3 proximal apical dendrites, which undergo atrophy as a result of repeated stress, we measured ultrastructural parameters associated with the mossy fiber-CA3 synapses in control and 21-day restraint-stressed rats. Whereas mossy fiber terminals (MFT) from control rats were packed with small, clear synaptic vesicles, terminals from stressed animals showed a marked rearrangement of vesicles, with more densely packed clusters localized in the vicinity of active synaptic zones. Moreover, compared with controls, restraint stress increased the area of the mossy fiber terminal occupied by mitochondrial profiles, a configuration which implies a greater, localized energy-generating capacity. A single stress session did not produce these changes either immediately after or the next day following the restraint session.

There are several implications of these findings. First, in MFT from stressed rats, the redistribution of vesicles and their localization near the active synaptic zones, together with more mitochondria, suggests that more vesicles may be available for glutamate release, although this possibility remains to be tested directly by electrophysiology and microdialysis (Magarinos, Verdugo Garcia, and McEwen, 1997). Second, the synaptic vesicle reorganization in MFT provides insights into possible molecular mechanisms of the effects of stress and stress mediators. Neurotransmitter release occurs at discrete active zones containing readily releasable pools of synaptic vesicles; this process requires fusion of vesicles with the presynaptic plasma membrane, and this membrane is retrieved and recycled for subsequent transmitter release (Bajjalieh and Scheller, 1996). Within the presynaptic compartment, synaptic vesicle-associated

phosphoproteins play a key role in regulating the efficiency of the neurotransmitter release from the nerve terminal. Synapsin I, in its dephosphorylated state, keeps the pool of "reserve" synaptic vesicles anchored to the nerve terminal cytoskeleton. Upon cell activation, Ca^{2+} /calmodulin-dependent protein kinase II mediates the phosphorylation of synapsin I, and the "reserve" pool of vesicles is freed from the cytoskeletal matrix, becoming available for neurotransmitter release (Peribone et al., 1997; Llinas et al., 1985; Greengard et al., 1993; Ceccaldi et al., 1995).

High levels of synapsin I protein and mRNA levels are present in the hippocampal MF terminal zone and granule cell neurons, respectively (Melloni et al., 1993; DeCamilli and Greengard, 1986). It is possible that the effect of repeated stress to cause clustering of vesicles close to the active zones could involve an increased expression of phosphorylated synapsin I. This has been observed in the hippocampus and parietal cortex of rats subjected to septal kindling, a model of synaptic plasticity that involves an increase in synaptic efficiency in response to repetitive local stimulations (Yamagata et al., 1995). It is noteworthy that brains of mice lacking the synapsin I gene show smaller mossy fiber terminals and a significant reduction in the number of synaptic vesicles that are not clustered but dispersed throughout the terminal (Takei et al., 1995).

The mossy fiber terminals reside on the proximal regions of the apical dendrites, and their numbers are not reduced in number by chronic stress (Magarinos, Verdugo Garcia, and McEwen, 1997). Therefore, the reduced number of CA3 apical dendritic branch points and total dendritic length observed in Golgi-impregnated material of repeatedly stressed rats and tree shrews might be interpreted as an adaptation to limit the increased excitatory input from recurrent axonal collaterals that are known to project from neighboring CA3 pyramidal neurons (Li et al., 1994; Ishizuka, Weber, and Amaral, 1990). Not only is there a recurrent excitatory input between CA3 pyramidal neurons that can be activated by the mossy fiber system, but also pyramidal neurons in subregion CA3c that lies closest to the hilus send excitatory axons back to the hilar region and affect the dentate gyrus itself (Scharfman, 1994; Kneisler and Dingledine, 1995). Such a feedback loop can presumably reactivate the mossy fiber system and sustain CA3 excitation, as in the so-called SPW or "sharp waves" (Buzsaki, 1986), and such an activation may drive the reorganization of vesicles within the mossy fiber terminals. Moreover, collateral activation of CA3 neurons by other CA3 neurons would help explain the blockade of dendritic atrophy by NMDA receptor blockade (Magarinos and McEwen, 1995), since the stratum lucidum of the

CA3 region does not express NMDA receptors (Monaghan et al., 1983).

CA3 pyramidal neurons display a high vulnerability not only to chronic stress but also to kainic acid administration, an effect that requires the integrity of the mossy fiber pathway (Nadler and Cuthbertson, 1980). As in the case of chronic restraint stress, CA3 region vulnerability is mediated by endogenous glucocorticoids and excitatory amino acid receptors (Armanini et al., 1990); and exogenous glucocorticoids have a potentiating effect (Sapolsky, 1986a, b; Packan and Sapolsky, 1990).

The CA3 hippocampal subregion is also damaged by epileptogenic stimulation of the perforant path, which involves the activation of the DG-MFT-CA3 pathway (Sloviter, 1993). Furthermore, in the epilepsy model, another parallel exists with the chronic stress model in the clustering of synaptic vesicles. It has been reported that synaptic vesicle clustering occurs in MFT of genetically prone epileptic gerbils, and this effect could be totally blocked by the disruption of the perforant pathway (Farias et al., 1992).

Accumulating data has linked epilepsy with excessive excitatory input, resulting in morphological alterations at the synaptic level. Well-characterized animal models of epilepsy, such as kindling and genetically epileptic mice, show that sprouting of mossy fibers generates a recurrent excitatory circuit involving aberrant granule cell-granule cell synapses (Sutula et al., 1996; Parent et al., 1997; Okazaki, Evenson, and Nadler, 1995). This possibility is supported by some electrophysiological evidence (C. Pavlides and B. S. McEwen, unpublished) and demands to be thoroughly tested, because it could account for an amplification of the excitatory input, and therefore, for the extreme sensitivity of mossy fibers to the stress paradigm.

In keeping with the reorganization of dendrites and alteration of synaptic vesicles in mossy fiber terminals, repeated stress produces a variety of effects on the electrophysiological features of the hippocampus (C. Pavlides and B. S. McEwen, unpublished). Forty-eight hours following 21 days of 6 hours-per-day repeated restraint stress, rats were studied under chloropent anaesthesia. Compared to control animals that were briefly handled but not subjected to the restraint stress, there was an inhibition of LTP in the lacunosum/molecular layer of CA3 of repeatedly stressed rats after stimulation of the commissural/associational pathway. The same inhibition of LTP was seen in the dentate gyrus granule cell layer with stimulation of the medial perforant pathway. The mossy fiber LTP was not affected by repeated stress.

There was another significant finding, namely, that high-frequency stimulation (HFS) produced epileptic afterdischarges in 38% of the repeatedly stressed rats,

while in the nonstressed controls HFS produced epileptic afterdischarges in only 15% of the animals. The rats showing seizures were removed from the analysis described in the previous paragraph. The increased incidence of seizures is consistent with increased mossy fiber sprouting (see preceding discussion).

In a second experiment, animals were subjected to a similar stress paradigm, and a current-source-density analysis was performed. In each of the hippocampal subfields, significant shifts between the control and stressed animals were observed in the sources and sinks.

Hippocampal function

Alterations in hippocampal circuitry and excitability affect a number of brain functions in which the hippocampus plays an important role. These include the regulation of hypothalamo-pituitary-adrenal (HPA) activity, episodic and declarative memory, spatial memory, and processing of emotional information. It is also important to consider the functional implications of sex differences in hippocampal function.

NEUROENDOCRINE REGULATION The hippocampus is involved in the regulation of HPA activity (Jacobson and Sapolsky, 1991), whereas the amygdala has a generally facilitative role (Prewitt and Herman, 1997; Roozendaal, Koolhaas, and Bohus, 1997; Bohus et al., 1996). Hippocampal lesions elevated cortisol secretion under a variety of stressful and nonstressful conditions (Jacobson and Sapolsky, 1991), although the results are not entirely consistent (e.g., see Bradbury, Strack, and Dallman, 1993; Jacobson and Sapolsky, 1991). Glucocorticoid implants into the hippocampus affect HPA activity in ways that are consistent with a feedback role of the hippocampus in HPA regulation (see Jacobson and Sapolsky, 1991). However, lesion and steroid-implant experiments also reveal an equally important role for the medial prefrontal cortex in HPA regulation (Diorio, Viau, and Meaney, 1993). The anatomical links from the hippocampus and medial prefrontal cortex to the hypothalamus are postulated to be via the bed nucleus of the stria terminalis and preoptic area, with an output from these structures to the paraventricular nucleus via inhibitory GABAergic projections (Herman and Cullinan, 1997).

A considerable amount of data has accumulated showing that elevated HPA activity is correlated with reduced levels of Type I or Type II receptors in the hippocampus (Jacobson and Sapolsky, 1991) or prefrontal cortex (Herman and Cullinan, 1997). In general, hippocampal Type I receptors are associated with the maintenance of basal ACTH and glucocorticoid levels

(Bradbury, Akana, and Dallman, 1994; Spencer, Moday, and Miller, 1997; DeKloet et al., 1998); forebrain Type II receptors are also associated with the containment of ACTH secretion (Spencer, Moday, and Miller, 1997; Bradbury, Akana, and Dallman, 1994), although a positive role of hippocampal Type II receptors has recently been reported (DeKloet et al., 1998). It is unclear whether correlations of hippocampal Type I and Type II receptor levels with HPA activity indicate a feedback action of adrenal steroids on the hippocampus, or a priming role for glucocorticoids to make the HPA axis optimally reactive to turning on and turning off a stress response, as suggested by recent studies by Dallman and colleagues (Akana et al., 1988).

Elevated and dysregulated HPA activity is seen in depressive illness, but the reasons for this elevation are not entirely clear. Dysregulation of the HPA axis associated with major depression is revealed by the dexamethasone suppression test (DST). Although the DST is most likely working at the pituitary level (Miller et al., 1992), the underlying dysregulation is undoubtedly of CNS origin and reflects increased drive upon the CRH and AVP systems of the hypothalamus (P. W. Gold et al., 1995) and constitutes a form of endogenously driven stress. A lessening of the adrenal steroid feedback effects on the hippocampus might be a contributing factor to elevated HPA activity in depression, and recent studies of Barden and coworkers with a transgenic mouse strain (Holsboer and Barden, 1996; Barden et al., 1997) have suggested that decreased forebrain Type II receptor expression might be a contributing factor to depression and a potential target of antidepressant therapy (Montkowski et al., 1995; Holsboer and Barden, 1996). It is not clear, however, how much hippocampal Type II receptor expression, as opposed to expression in other brain regions, is a key factor.

There is another linkage of the hippocampus with elevated cortisol levels. Recent studies using MRI imaging have indicated that elevated cortisol levels are associated with some shrinkage of the hippocampal formation and mild cognitive impairment (Lupien et al., 1998; Sheline et al., 1996; Axelson et al., 1993; Starkman et al., 1992). This topic will be discussed in the next subsection.

ADRENAL STEROIDS, STRESS, AND HIPPOCAMPALLY DEPENDENT MEMORY In animal models, adrenal steroids acutely modulate memory formation through their actions on excitability. Type I receptor activation has been associated with enhanced attention and improved acquisition, whereas Type II receptor activation shows a biphasic effect on memory performance, with low doses of adrenal steroids facilitating and high doses inhibiting the retention of memories dependent on hippocampal

function (Lupien and McEwen, 1997). Single stressful episodes also affect memory (Diamond et al., 1996) and appear to do so via adrenal steroids (Diamond et al., 1996) as well as other pathways (Shors, Seymour, and Thompson, 1990).

Chronically, repeated stresses also cause memory impairment, presumably through their ability to cause dendritic atrophy and suppression of neurogenesis. Functional studies of repeatedly stressed rats revealed impairments in two different tests of hippocampally dependent spatial memory. In an eight-arm radial maze in rats, 21 days of restraint stress prior to maze training led to impaired acquisition and larger numbers of errors, but only when rats were trained and evaluated immediately after the end of the stress sequence; 18 days later, the acquisition was normal (Luine et al., 1994). This impairment was in the same direction, but not as great, as impairment found in aging rats; moreover, stress effects were prevented by prior treatment of rats with phenytoin or with tianeptine under the same conditions in which phenytoin was able to prevent the stress-induced atrophy of CA3 pyramidal neurons (Luine et al., 1994; Watanabe, Gould, Cameron, et al., 1992).

In a subsequent study, a spatial recognition memory task in a Y-maze was used to demonstrate an impairment in rats that received 21 days of restraint stress and were tested immediately at the end of stress (Conrad et al., 1996). Tianeptine treatment prior to daily stress prevented the impairment (Conrad et al., 1996), just as it had prevented the dendritic atrophy. A more recent study examined contextual fear conditioning and found that repeated restraint stress did not impair, but rather enhanced, both tone- and context-dependent fear conditioning (C. Conrad, A. Magarinos, J. Ledoux, and B. S. McEwen, unpublished).

Studies on the tree shrew have shown that 28 days of psychosocial stress impair spatial memory in a modified hole board test (Gould et al., 1997). It should be noted that we have to consider changes in dentate gyrus neurogenesis in explaining memory impairment.

In humans, there is evidence for cognitive impairment associated with adrenal steroid treatment (Newcomer et al., 1994; Wolkowitz, Reuss, and Weingartner, 1990; Wolkowitz, Rubinow, and Doran, 1990; Martignoni et al., 1992). In the most recent of these studies, dexamethasone was given for four consecutive days at 23:00, and cognitive testing was performed at 14:00 on study days 0, 1, 4, and 7 after the last treatment (Newcomer et al., 1994). There was decreased declarative memory recall on study day 4 and day 7 after the last treatment in the DEX-treated subjects compared to placebo-treated subjects (Newcomer et al., 1994). No other cognitive measures were affected by DEX, indicating the specificity to

a task that is known to involve hippocampal-temporal lobe function. Because the poorest performance was found on study day 4, along with the lowest levels of endogenous cortisol, it is impossible to say whether the cognitive deficit is associated with the action of DEX on the brain or the reduction in cortisol. Since glucocorticoids have biphasic effects on synaptic plasticity (Pavlidis, Watanabe, et al., 1995; Diamond et al., 1992; see "Stress, Adrenal Steroids, and Neuronal Excitability" subsection), which are thought of as neurophysiological models of information storage processes (Bliss and Collingridge, 1993, either explanation is plausible.

Another study employed a bolus injection of cortisol and reported declarative memory deficits acutely after treatment (Kirschbaum et al., 1996). Such bolus administration of cortisol impairs glucose uptake in hippocampus (de Leon et al., 1997), and this action may represent a mechanism for acute memory impairment by glucocorticoids because of the well-known facilitation of memory mechanisms by glucose administration (P. E. Gold, 1987).

Chronically, stressful conditions and elevated HPA activity are associated with selective atrophy in the human brain, based upon MRI imaging. The conditions in which hippocampal atrophy has been reported include Cushing's syndrome, posttraumatic stress disorder, recurrent depressive illness, normal aging preceding dementia, and Alzheimer's disease (McEwen, 1997). Hippocampal shrinkage is usually accompanied by deficits in declarative, episodic, spatial, and contextual memory performance, and the hippocampal changes provide a neural substrate for changes in cognitive function that have been recognized to accompany these various conditions. The hippocampus has long been known as a target of stress hormones, and it is an especially plastic and vulnerable region of the brain. However, the prominence of the hippocampus as a glucocorticoid target has obscured the fact that other factors besides glucocorticoid hormones are involved in the process of hippocampal atrophy. Excitatory amino acids and NMDA receptors are prominent in their involvement in an animal model of hippocampal atrophy as well as in neuronal death. Furthermore, the finding of hippocampal atrophy does not necessarily imply a permanent loss of cells, and this aspect deserves careful investigation, both to analyze the underlying anatomical changes and to investigate the possibility of pharmacological treatment to reverse the process. In cases where atrophy is due to cell loss, the time course of the disease process will provide much useful information about mechanism and offer the possibility of early intervention to arrest or slow the pathological process.

HIPPOCAMPAL FUNCTION IN DEVELOPMENT AND AGING The vulnerability of many systems of the body to stress is influenced by experiences early in life. In animal models, unpredictable prenatal stress causes increased emotionality and increased reactivity of the HPA axis and autonomic nervous system, and these effects last throughout the life span. Postnatal handling in rats, a mild stress involving brief daily separation from the mother, counteracts the effects of prenatal stress and results in reduced emotionality and reduced reactivity of the HPA axis and autonomic nervous system. The vulnerability of the hippocampus to age-related loss of function parallels these effects—prenatal stress increasing and postnatal handling decreasing the rate of brain aging. Concurrently, age-related decline of gonadal function reduces the beneficial and protective actions of these hormones on brain function. At the same time, age-related increases in adrenal steroid activity promote age-related changes in brain cells that can culminate in neuronal damage or cell death. Lifelong patterns of adrenocortical function, determined by early experience, contribute to rates of brain aging, at least in experimental animals.

Unpredictable or uncontrollable stressful experiences of a pregnant rat increase emotionality and stress hormone reactivity in offspring that last for the lifetime of the individual, whereas the gentle and repeated stimulation of newborn rat pups known as postnatal handling produces reductions in emotionality and stress hormone reactivity that also last a lifetime (Vallee et al., 1997; Meaney et al., 1988; Fride et al., 1986; Levine et al., 1967; Denenberg and Haltmeyer, 1967; Ader, 1968). These effects appear to involve mediation by both the mother's behavior and by adrenal and thyroid hormone actions. More is known about the mechanism of neonatal handling. Handling involves separating the pups from the mother for 10 minutes per day for the first two weeks of neonatal life, and the licking of the pup by the mother appears to be an important determinant of the postnatal handling effect (Liu et al., 1997). At the same time, increasing corticosterone levels in the mother's milk mimic some of the effects of neonatal handling (Catalani et al., 1993), and thyroid hormone elevations have been suggested as a possible mediator of the neonatal handling effect, particularly regarding the elevated expression of glucocorticoid receptors in the hippocampus (Meaney, Aitken, and Sapolsky, 1987).

Studies in which both prenatal stress and postnatal handling were compared indicate that these two procedures have opposite effects on food intake, body weight, and anxiety, as well as HPA activity (Vallee et al., 1996, 1997). However the two processes interact, in that prenatal stress effects on HPA activity and emotionality are

reversed by early postnatal "adoption" or cross-fostering of pups to new mothers (Barbazanges, Vallee, et al., 1996; Maccari et al., 1995), which is most likely a form of postnatal handling involving intense licking of the pup by the mother (Liu et al., 1997). Prenatal stress during the last week of gestation in rats increases reactivity of the HPA axis and reduces expression of the Type I adrenal steroid receptor in hippocampus, which help to contain basal levels of HPA activity (Vallee et al., 1996; Henry et al., 1994). Prenatal stress also increases anxiety in an open field test and decreases basal food intake and body weight (Vallee et al., 1996, 1997). It is important to note that some of these prenatal stress effects may involve a mediation by adrenal steroids (Barbazanges, Piazza, et al., 1996). Taken together with the fact that postnatal handling effects may also be mimicked by adrenal steroids (Catalani et al., 1993), the specific effects of adrenal steroids on the neural development of emotionality and HPA reactivity may change qualitatively as the nervous system matures.

For prenatal stress and postnatal handling, once the emotionality and the reactivity of the adrenocortical system are established by events early in life, it is the subsequent actions of the hypothalamo-pituitary-adrenal (HPA) axis in adult life that play a major role in determining the rate of brain and body aging. Increased HPA activity is associated with increased brain aging, whereas the opposite is true of animals with reduced HPA reactivity to novel situations. Rats with increased HPA reactivity show early decline of cognitive functions associated with the hippocampus (Dellu et al., 1994) as well as increased propensity to self-administer drugs such as amphetamine and cocaine (Deroche et al., 1993; Piazza et al., 1994). In contrast, rats with a lower HPA reactivity as a result of neonatal handling have a slower rate of cognitive aging and a reduced loss of hippocampal neurons and function (Meaney et al., 1994; Catalani et al., 1993).

With regard to the natural process of aging, long-term stress also accelerates a number of biological markers of aging in rats, including increasing the excitability of CA1 pyramidal neurons via a calcium-dependent mechanism and causing loss of hippocampal pyramidal neurons (Koprowski et al., 1993). An important factor may be the enhancement by glucocorticoids of calcium currents in hippocampus (D. S. Kerr et al., 1992), in view of the key role of calcium ions in destructive as well as plastic processes in hippocampal neurons.

We have seen that adrenal steroids affect the structure and function of the hippocampus in a variety of ways, and we have also seen that, in human subjects, there is evidence for both cognitive impairment and hippocampal atrophy associated with altered levels of adrenal ste-

roids. What are the possible mechanisms for these changes? As discussed previously, the acute inhibition of LTP and PBP by high levels of glucocorticoids represents one mechanism by which this process might occur, while the atrophy of rat hippocampal CA3 neurons after either repeated stress or repeated glucocorticoid treatment, along with the reported atrophy of the hippocampus of Cushing's patients and depressed subjects, constitutes a long-term mechanism for cognitive impairment.

Another aspect of the relationship between adrenal steroid levels, cognitive function and hippocampal volume is illustrated by studies of basal cortisol levels and cognitive deficits in human aging (Lupien et al., 1994, 1998). Aged subjects followed over a four-year period, who showed a significant increase in cortisol levels over the four years and had high basal cortisol levels in year 4, showed deficits on tasks measuring explicit memory as well as selective attention, compared to subjects with either decreasing cortisol levels over four years or subjects with increasing basal cortisol but moderate current cortisol levels (Lupien et al., 1994). They also showed a hippocampus that was 14% smaller than age-matched controls who did not show progressive cortisol increases and were not cognitively impaired (Lupien et al., 1998). Thus, once again, the question of acute versus chronic effects of cortisol is unsettled as a primary cause, and both types of mechanisms may apply. However, this study evokes the model called the glucocorticoid cascade hypothesis (Sapolsky, Zola-Morgan, and Squire, 1991), in which rising cortisol levels compromise the hippocampus by destroying neurons and contribute to cognitive impairment as well as reducing the inhibitory effect of the hippocampus on cortisol secretion. Consistent with this hypothesis is the fact that lesions of the fornix or the hippocampal formation-temporal lobe region of *Cynomolgus* monkeys produced an elevation of cortisol secretion for at least six months postlesion (Sapolsky, 1992; Sapolsky, Krey, and McEwen, 1986).

A final point to be made about adrenal steroids, stress, and the hippocampus is that adrenal steroids do not act alone. Rather, we have seen that both excitatory amino acids and serotonin release, possibly facilitated by circulating glucocorticoids, play a key role. In fact, the final common path for CA3 dendritic atrophy in rats treated with either corticosterone or by restraint stress involves processes that are blocked by blocking glutamate release or actions using phenytoin or an NMDA antagonist, respectively, or by facilitating serotonin reuptake using tianeptine. The efficacy of these agents raises the attractive possibility of treating individuals—perhaps the depressed elderly—with agents such as phenytoin or tianeptine as a means of

improving cognitive function. If such studies are carried out, it will be important to determine the degree to which hippocampal volume may be increased by such treatments and whether long-term treatment protects these same individuals from dementia.

EFFECTS OF ESTROGENS ON LEARNING AND MEMORY It has been difficult to detect cyclicity of performance in spatial tasks, with no effect reported (Berry, McMahan, and Gallagher, 1996), with differences reported in motivational or attentional parameters (Blasberg et al., 1996), or with an impairment reported in performance on proestrus (Frye, 1995). This lack of agreement and paucity of effects may be a reflection of the relative insensitivity of the measures used to detect behaviors that female rats actually use in their natural environments at the time of mating. However, some success has resulted from studying longer-term effects of ovariectomy and estrogen replacement on hippocampal-dependent learning and memory.

Three types of effects have been reported in animal models. First, E treatment of ovariectomized female rats has been reported to improve acquisition on a radial maze task as well as in a reinforced T-maze alternation task (Daniel et al., 1996; Fader, Hendricson, and Dohanich, 1996). Second, sustained E treatment is reported to improve performance in a working memory task (O'Neal et al., 1996) as well as in the radial arm maze (Luine et al., 1996; Daniel et al., 1996). Third, E treatment is reported to promote a shift in the strategy that female rats use to solve an appetitive two-choice discrimination, with E treatment increasing the probability of using a response as opposed to a spatial strategy (Korol et al., 1996). Fourth, aging female rats that have low E plasma levels in the "estropause" are reported to perform significantly worse in a Morris water maze than female rats with high E levels (Juraska and Warren, 1996).

The effects of estrogen replacement in rats are reminiscent of the effects of E treatment in women whose ovarian function has been eliminated by surgical menopause or by a GnRH antagonist used to shrink the size of fibroids prior to surgery (Sherwin and Tulandi, 1996; Robinson et al., 1994; Sherwin, 1994). In general, these effects are seen within a number of weeks and are reversible. Another aspect of estrogen action in the aging brain is that E treatment of postmenopausal women appears to have a protective effect on the brain with regard to Alzheimer's disease (Tang et al., 1996; Henderson, Watt, and Buckwalter, 1996; Paganini-Hill and Henderson, 1994; Henderson et al., 1994; Birge, 1994). It is likely that these protective actions involve a number of other actions of estrogens besides inducing synapses. These include suppression of the production of the toxic

form of beta amyloid protein (Jaffe et al., 1994) and inhibition of free-radical-induced toxicity (Grindley, Green, and Simpkins, 1997; Behl et al., 1997). It should also be noted that estrogens affect many regions of the brain, including the basal forebrain cholinergic systems, the serotonergic system, the dopaminergic system, and the noradrenergic system (for review, see McEwen et al., 1997; McEwen et al., 1995).

IMPORTANCE OF SEX DIFFERENCES Sex differences in brain structures and mechanisms occur in other brain regions besides hypothalamus, such as hippocampus, and they appear to be involved in aspects of cognitive function and other processes that go beyond the reproductive process itself, such as the higher incidence of depression in women and of substance abuse in men (Regier et al., 1988). There are also sex differences in the severity of brain damage resulting from transient ischemia (Hall, Pazara, and Linseman, 1991) and sex differences in the response of the brain to lesions (Morse, Dekosky, and Scheff, 1992) and to severe, chronic stress (Mizoguchi et al., 1992; Uno et al., 1989). A recent study has shown that the stress-induced atrophy of apical dendrites of CA3 pyramidal neurons occurs in male rats but not in female rats (Galea et al., 1997). What is not yet clear in this case is whether this atrophy, which is reversible, increases or decreases the vulnerability of the male and female brain to permanent damage.

Conclusions

The hippocampus is a brain site of considerable plasticity, directed by hormones but also involving endogenous excitatory amino acids and NMDA receptors, along with other transmitters. Because the hippocampus performs a similar behavioral role in animals and in humans, what we learn from studies of hormone effects in animals is directly applicable to the human condition. The best examples are the changes in hippocampal volume in humans, detected by MRI, which can be evaluated in terms of the known mechanisms by which stress and stress hormones regulate neurogenesis in the dentate gyrus, dendritic remodeling in the CA3 region, and pyramidal neuron survival. Not all conditions involving hippocampal atrophy need to involve the same detailed neuroanatomical changes—some may involve permanent damage, whereas others may involve potentially reversible changes in the dentate gyrus or Ammon's horn. Yet all these instances of atrophy involve deficits in declarative and spatial memory, which can be found not only in humans but also in animal models in which some form of hippocampal atrophy or damage has been produced.

Another example of the transferability of information between animal models and human subjects pertains to the actions of estrogens on declarative memory in humans that were stimulated by and predicted from the findings in animals that estrogens regulate the formation of excitatory spine synapses in the hippocampus. Indeed, there are studies in humans that show rapid and reversible effects of estrogen deprivation and replacement on verbal memory. Moreover, the study of the neuroprotective actions of estrogens has arisen from animal model studies of the diverse actions of estrogens on nonreproductive systems of the brain, as well as models of neurotoxicity and the amyloid precursor protein.

Sex differences and the process of sexual differentiation constitute another major area of convergence of animal and human studies of hippocampal function. The intriguing sex differences in hippocampal morphology and spatial learning and memory seen in rats are reminiscent of sex differences in human neuropsychological studies with respect to strategies used to solve spatial navigation problems. Equally important for their implications are the sex differences in vulnerability of the hippocampal formation of animals to atrophy and damage from severe stress. At present, there are hints from human clinical studies of differential vulnerability of the male and female human brain to a variety of insults, and much more investigation needs to be done in this regard in terms of the protective efficacy of gonadal hormone replacement therapy in the aging human brain.

Finally, studies of the plasticity of the hippocampus provide a very useful and productive system in which to explore fundamental processes of neurogenesis, synaptogenesis, and dendritic remodeling in the context of highly relevant situations of adaptive plasticity of the adult brain. The studies described in this chapter will provide an excellent foundation for a new generation of investigations of these various forms of plasticity, using transgenic animal models as well as cell culture systems.

ACKNOWLEDGMENTS Research support for studies in the author's laboratory was provided by NIH grants MH43156 and NS07080 as well as the Health Foundation, New York, and Servier, France. The author wishes to thank his many colleagues and collaborators for their many contributions.

13 Activity and the Development of the Visual Cortex: New Perspectives

LAWRENCE C. KATZ, MICHAEL WELIKY, AND JUSTIN C. CROWLEY

ABSTRACT Although development of cortical functional architecture has been widely viewed as an activity-dependent process strongly influenced by environmental cues, a growing body of research indicates that the initial establishment of cortical circuits takes place without the influence of visual experience. Increasing attention has focused on the possible roles of spontaneous activity in providing the instructive cues necessary to construct cortical circuits. New recording and stimulation techniques that allow recording and manipulation of spontaneous activity in vivo demonstrate that spontaneous activity in the developing visual pathway exhibits several features inconsistent with simple correlation-based models of cortical development. Moreover, manipulations of endogenous patterns reveal that the initial establishment of ocular dominance and orientation columns is surprisingly resistant to changes in the correlational structure of spontaneous activity. The current emphasis on correlation-based models, which may be appropriate for later plastic changes, could be obscuring the role of intrinsic signals that guide the initial establishment of functional architecture.

Since the pioneering work of Hubel and Wiesel some 30 years ago, development of the functional architecture of the mammalian striate cortex has served as a kind of Rosetta stone for understanding the influences of neuronal activity and environment on the construction and modification of brain circuitry (Wiesel, 1982). Historically, greatest attention has been paid to the mechanisms by which established patterns of neural circuits, such as ocular dominance columns, are modified by visual experience during restricted “critical periods” early in postnatal life (Hubel and Wiesel, 1970; Wiesel and Hubel, 1965a). The well-documented effects of monocular deprivation (Wiesel and Hubel, 1965b) and strabismic rearing (Hubel and Wiesel, 1965) make a compelling argument for the role of visual experience

and the resulting patterns of neuronal activity in eliciting rearrangements of functional connections. Currently popular theories for how such plastic rearrangements take place focus on the role of correlated neuronal activity and its effects on synaptic strength, perhaps mediated by NMDA-receptor-dependent mechanisms such as long-term potentiation (see Bear and Kirkwood, 1993, for review).

However, it has been less appreciated that the establishment of orientation and ocular dominance columns has at least two distinct phases: the initial establishment of a certain pattern of connectivity, and a subsequent stage during which plastic modifications of existing patterns are possible. The rules and mechanisms guiding these two phases need not be identical. For example, the work of Rakic (1977) and more recently Horton and Hocking (1996) demonstrates that geniculocortical afferents, which form the anatomical underpinning of ocular dominance columns, segregate into eye-specific stripes before birth and before any patterned visual experience is possible. Similarly, early work by Hubel and Wiesel in cats and monkeys (Hubel and Wiesel, 1963; Wiesel and Hubel, 1974) and more recent work in cats (Godecke and Bonhoeffer, 1996) demonstrate that orientation tuning and binocularly aligned maps of orientation columns develop in the absence of visual input.

It seems likely that the key to understanding how cortical architecture is first constructed is to understand how geniculocortical afferents are patterned within layer 4 of the developing cortex. Obviously the segregation of geniculocortical afferents into eye-specific stripes—the basis of ocular dominance columns—takes place in layer 4. In addition, however, there is good evidence that the spatial arrangement of geniculocortical afferents provides a basic outline of orientation selectivity in cortex (Chapman, Zahs, and Stryker, 1991; Ferster, Chung, and Wheat, 1996; Ferster and Koch, 1987; Reid and Alonso, 1995; Sompolinsky and Shapley, 1997). In modeling studies, developmental rules based on patterns of activity and local correlations can produce arrangements of geniculocortical inputs that mimic those actually observed (Linsker, 1986a, 1986b; Miller, 1994a;

LAWRENCE C. KATZ Howard Hughes Medical Institute and Department of Neurobiology, Duke University Medical Center, Durham, N.C.

MICHAEL WELIKY Center for Visual Science, University of Rochester, Rochester, N.Y.

JUSTIN C. CROWLEY Howard Hughes Medical Institute and Department of Neurobiology, Duke University Medical Center, Durham, N.C.

Swindale, 1982, 1992). Ideally, therefore, one would like to know the actual patterns of activity in the output neurons of the developing thalamus and in layer 4 of cortex.

Spontaneous activity in the developing visual pathway

The realization that spontaneous activity in developing systems could provide cues necessary for anatomical rearrangements (Stryker and Harris, 1986) provided an important conceptual shift that helped resolve the apparent contradiction between the observation that cortical architecture emerged without visual experience and the observation that it could be modified by such experience. The importance of spontaneous activity has been demonstrated most clearly in the development of eye-specific layers in the cat lateral geniculate nucleus (LGN). Inputs from the two eyes initially overlap in the developing thalamus and gradually segregate into eye-specific layers well before birth. This segregation depends on neuronal activity: Pharmacologically silencing the thalamus or the eyes prevents segregation into separate layers (Sretavan and Shatz, 1986b; Sretavan, Shatz, and Stryker, 1988).

Experiments in the developing retina have provided the bulk of the data available regarding the patterns of spontaneous activity present along the developing visual pathway. In their pioneering experiments Maffei and Galli-Resta (1990) recorded from retinal ganglion cells in prenatal rat pups, using an ex utero preparation. Even before eye opening (and before photoreceptor cells were generated) they observed that retinal ganglion cells were producing regular, spontaneous bursts of action potentials, and that these bursts were highly correlated among nearby neurons. An extensive series of subsequent investigations by Shatz and colleagues used innovative combinations of multielectrode recordings and optical recordings in vitro to demonstrate that retinal activity actually consisted of local waves of activity propagating across limited portions of the retina. At any given time, a relatively small portion of the retina is spontaneously active, but over time the waves essentially "tile" the developing retina (Feller et al., 1997; Meister et al., 1991; Wong, Meister, and Shatz, 1993).

Because the two eyes have no direct connections between them, spontaneous, periodic waves in the two retinas create two independent oscillators. From the standpoint of correlation-based theories of axon segregation, this fact provides an ideal cue for segregating eye-specific layers in the LGN—the activity of groups of retinal ganglion cells from one eye will be well correlated with the activity of nearby cells, while the patterns of activity of groups of retinal ganglion cells from the other

eye will be essentially uncorrelated. In three-eyed frogs the uncorrelated patterns of activity in the normal and ectopic eyes are sufficient to drive segregation of retinotectal terminals into patterns greatly resembling ocular dominance columns (Constantine-Paton and Law, 1978; Law and Constantine-Paton, 1981; Reh and Constantine-Paton, 1985).

Theoretically, such uncorrelated patterns of activity would be ideal not only for segregating layers in the LGN, but also for segregating geniculocortical afferents into eye-specific stripes in layer 4 of the visual cortex. Recordings in rodents (Mooney et al., 1996) suggest that the patterns of waves observed in the retina cause thalamic neurons to fire in similar patterns, thus providing an obvious route for retinal waves to influence geniculocortical termination patterns.

However, despite the suggestive simplicity of such condition-based models, it is not always possible to predict the actual patterns of spontaneous activity driving the cortex in vivo by extrapolating from the patterns present in the retina in vitro. While patterns within the retina itself are immune to modification by connections with the rest of the central nervous system, patterns of spontaneous activity in the thalamus and cortex are shaped by retinal input and by local circuits within each structure, and by feedback connections between different regions. In the LGN, for example, retinal inputs provide only a small proportion—under 15%—of synaptic inputs (Guillery, 1969a, 1969b). Intrinsic GABAergic interneurons, inhibitory inputs from the thalamic reticular nucleus, and feedback connections from layer 6 of primary visual cortex comprise a significant proportion of the synapses. In addition, numerous other brainstem structures provide significant neuromodulatory inputs, especially acetylcholine but also noradrenaline and serotonin (see Sherman and Koch, 1998, for a recent review).

Thus, while it is convenient and appropriate to study spontaneous patterns of retinal activity in an in vitro model of the isolated retina, this approach cannot reveal the transformations that retinal activity may undergo at subsequent stages in the visual pathway. Hence it is important to determine the patterns of spontaneous activity in the developing thalamus in vivo.

Patterns of spontaneous activity in the developing thalamus in vivo

By using multielectrode extracellular recordings, it is possible to record spontaneous activity in the developing thalamus of awake, behaving ferrets (Weliky and Katz, in press). The ferret LGN has a stereotyped organization, with contralateral and ipsilateral inputs segregated into distinct layers (layers A and A1, respectively). Within

each layer, retinal axons are segregated by response subtype, such that ON-center and OFF-center ganglion cells terminate in distinct sublaminae. Thus, with an array of eight closely spaced microwires, spontaneous activity can be simultaneously recorded across eye- and response-type-specific layers. As these inputs are functional well before eye opening, visually evoked responses allow the exact location of each electrode to be determined.

Ferrets typically open their eyes around postnatal day 34. Cortical cells become visually responsive (although the eyes are still closed) by about day 21, and retinal waves are observed in vitro up until about day 30 (Wong, Meister, and Shatz, 1993). Recordings of spontaneous activity in awake, behaving ferrets in vivo between day 21 and 26 reveal robust, patterned spontaneous activity that superficially resembles the patterns of retinal activity observed in vitro. Activity consists of periodic, high-frequency bursts lasting several seconds, followed by 20–30 seconds of quiescence (figure 13.1). Interestingly, these patterns are observed only in unanesthetized animals. Even very low concentrations of inhalation anesthetics (such as isoflurane) completely abolish this spontaneous activity. However, the level and pattern of activity appear insensitive to the animal's overall behavioral state, and do not change dramatically whether the animals are quietly resting or actively exploring their environment.

As might be expected from patterns of retinal activity, analysis of the correlational structure of thalamic spontaneous activity showed that activity within each individual eye-specific layer was highly correlated. The highest correlations occurred between groups of neurons that shared inputs from the same eye and from the same retinal ganglion cell receptive field type (i.e., ON or OFF center). However, in addition to these expected types of correlations, significant binocular correlations were also observed, which were much too high to be generated by independent periodic events in the two retinas. Ablation of the ipsilateral visual cortex specifically abolished the binocular correlations, while leaving the within-eye correlations and patterned activity intact (figure 13.2).

Thalamocortical loops and the generation of patterned spontaneous activity

Most models of the development of cortical functional architecture are based on activity-dependent changes in synaptic connectivity that depend on the levels of correlation between competing groups of afferents. If one accepts this theoretical standpoint, developing thalamocortical axons must satisfy at least two constraints: inputs from the two eyes must be sufficiently uncorrelated such that they segregate into eye-specific domains (ocular dominance columns) yet have sufficient correlation such

that the maps of orientation selectivity are identical in the two eyes (Miller, 1994b; Swindale, 1992, 1996).

The patterns of spontaneous activity in the thalamus appear to meet these basic requirements. In particular, the requisite binocular correlations, which could potentially be generated via any number of local or extrinsic circuits, are specifically mediated by corticothalamic feedback. In the adult, the role of the layer 6 feedback connection to the thalamus has a long, rich, and controversial history. In some studies (Schmielau and Singer, 1977) this connection has been implicated in binocular visual processing and in establishing correlations between nearby cells (Sillito et al., 1994). These results from anesthetized adult animals, especially the role in binocular vision, are certainly consistent with the apparent role of corticothalamic feedback in neonatal animals.

Even in the absence of retinal inputs, the thalamocortical loop sustains robust spontaneous oscillatory activity. If both optic nerves are severed, leaving the thalamocortical connection intact, all spontaneous thalamic activity ceases for several hours. After this time, however, highly correlated, high-frequency bursts of action potentials return (Weliky and Katz, in press) (figure 13.3). Unlike bursts driven by retinal activity, these bursts are very highly correlated across eye-specific layers, although correlations within each eye-specific layer remain the strongest. Nevertheless, even in the absence of retinal input, including drive by retinal waves, highly structured periodic activity is generated. Although the isolated thalamus itself, later in life, sustains oscillatory activity (McCormick, Trent, and Ramoa, 1995), in these younger animals patterned activity results from thalamocortical interactions, as ablation of the cortex completely obliterated bursts. In the thalami of animals with both optic nerves cut and the ipsilateral cortex ablated, the remaining activity consists of isolated, random spikes with no detectable correlations between recording sites.

Thus removing the eyes does not eliminate patterned activity in the developing thalamocortical projection, but does dramatically alter its correlational structure, producing activity patterns in which the two eye-specific layers are much more correlated than normal. This observation is significant for interpreting further experiments on the development of cortical functional architecture, which will be discussed in later sections (see "Activity and the development of ocular dominance columns: A reconsideration").

A contralateral eye bias in patterning thalamic spontaneous activity

From the standpoint of activity in the two retinas, there is no reason to suspect differences in the level or pattern of

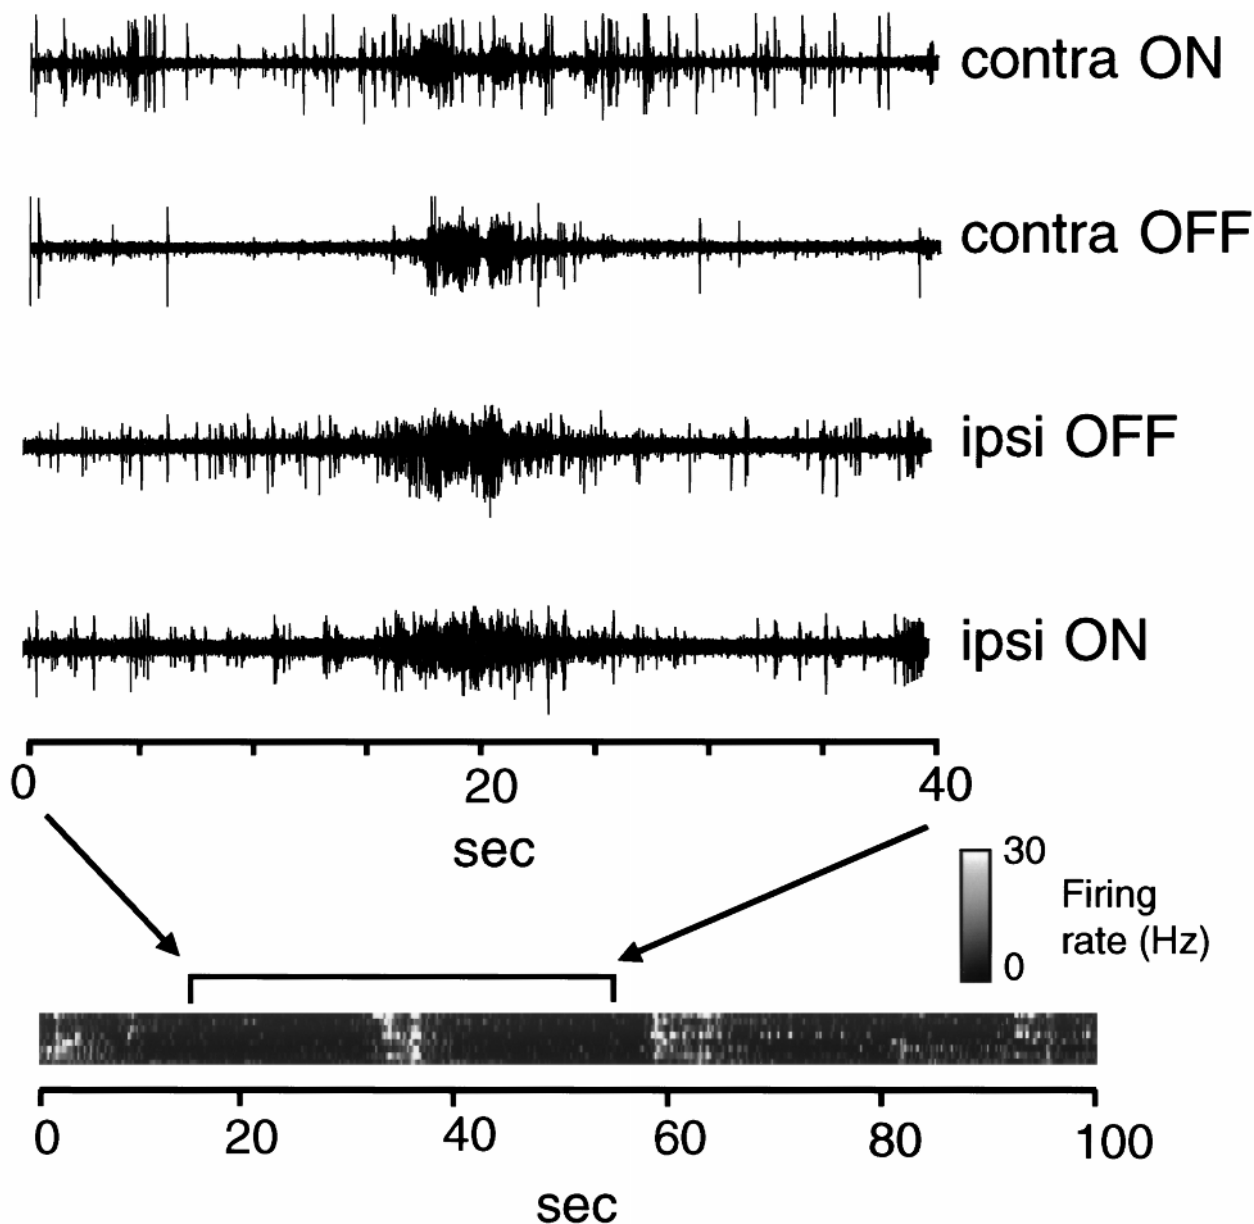

FIGURE 13.1 Spontaneous activity in the lateral geniculate nucleus (LGN) of an awake behaving ferret, approximately 1 week prior to eye opening. The top four traces show neural activity recorded on four different electrodes of an eight-electrode array. Each electrode is located in a different eye-specific LGN layer (ipsi: the eye on the same side as the recording array; contra: the eye contralateral to the array) and response-type-specific layer (i.e., ON center and OFF center), as identified by visual stimulation. Spontaneous activity consists of bursts of action potentials, lasting a few seconds, at roughly 20-

activity emerging from the two eyes. Yet there are reasons to suspect that the contributions of the two eyes in driving downstream circuits in the thalamus and cortex are not necessarily equal. For example, the first orientation-selective cells in the developing cortex are driven exclusively by the contralateral eye. Even more dramatically, optically imaged orientation maps are first observed only when the

second intervals. In the lower portion of the figure, the spike rate at each of the eight electrodes is represented in gray scale; in these time-series graphs bursts are apparent as zones of white. Within the 100-second-long recording illustrated, four bursts occurred. There are clear correlations in the firing patterns across all layers and receptive-field types, although the correlations are highest between electrodes of the same ocularity and receptive field subtype. (Modified from Weliky and Katz, in press.)

contralateral eye is stimulated, and these responding cells seem to be already grouped into zones—columns—of contralaterally dominated inputs, even when ipsilaterally driven responses are absent (Crair, Gillespie, and Stryker, 1998; Godecke et al., 1997).

In the thalamus, contralateral inputs from the retina reach the thalamus a few days before ipsilateral inputs,

FIGURE 13.2 Histograms of the correlation coefficients in all experiments. With the ipsilateral cortex intact, the strongest correlations are between electrodes that share the same ocularity and receptive field subtype; however, highly significant correlations are present between the two eyes (compare “Between eye” to “Randomized,” which shows the absence of correlations when these same spike trains are randomly shifted in time). Aspiration of the visual cortex specifically abolishes binocular correlations while leaving the within-eye correlations unaffected. (Modified from Weliky and Katz, in press.)

although the two sets spatially overlap prior to segregation of eye-specific layers. In recordings from older animals, activity patterns emerging from the contralateral eye dominate, and may in fact determine, the patterns of spontaneous activity in the thalamus (and by implication, in the cortex as well) (Weliky and Katz, in press). If the ipsilateral optic nerve is severed during the period of spontaneous bursting, the overall level and pattern of

spontaneous activity remains virtually unchanged. In contrast, if the contralateral optic nerve is cut, the pattern of activity in the thalamus rapidly assumes the temporal structure of spontaneous activity seen when both optic nerves are cut simultaneously (figure 13.3). Thus, the ipsilateral retinal ganglion cells appear incapable, on their own, of driving spontaneous activity in the thalamus. In the presence of ipsilateral retinal activity alone, the system is strongly dominated by the thalamocortical loop described earlier, and the resulting activity is highly correlated among all electrodes.

Although it is unclear how early this contralateral bias develops, it is in place before eye opening and well before segregation of ocular dominance columns. This bias at the level of the thalamus is probably the basis of the early development of contralateral visual responses in the cortex, and perhaps for the observations that ocular dominance columns representing the contralateral eye appear to be wider even in animals without visual experience (Tychsen and Burkhalter, 1997). As has been pointed out previously (Crair, Gillespie, and Stryker, 1998) this initial bias presents several significant challenges to the standard Hebbian models of ocular dominance column formation. According to current dogma, representations of the two eyes start out equivalent, as indicated by overlapping patterns of geniculocortical input from the two eye-specific layers (LeVay, Stryker, and Shatz, 1978; LeVay, Wiesel, and Hubel, 1980). By a correlation-based process of competition, involving

FIGURE 13.3 Time series graphs following manipulations of thalamic input. Under control conditions (top two panels), bursts occur approximately every 20 seconds and last for several seconds; usually only a subset of electrodes are active at any given time. Cutting the ipsilateral optic nerve (middle two panels) has virtually no effect on the pattern of bursting. When both optic nerves are severed, however, the pattern of LGN bursting changes dramatically: Now activity is observed on all electrodes during a burst; the bursts are shorter and occur more frequently

and regularly. Remarkably, these effects are not symmetric, for cutting the contralateral optic nerve first (bottom two panels) immediately causes the pattern of spontaneous activity to resemble that seen after severing both nerves. Cutting the ipsilateral optic nerve does not change the pattern further. Thus it appears that the bursting pattern is driven primarily by inputs from the contralateral optic nerve, and inputs from the ipsilateral optic nerve are by themselves incapable of driving thalamic activity. (Modified from Weliky and Katz, in press.)

strengthening of coactive inputs (presumably from the same eye) and weakening of uncorrelated inputs (from different eyes), ocular dominance stripes are thought to emerge gradually. However, if the inputs from the contralateral and ipsilateral eyes are not equivalent—and, specifically, if those from the contralateral eye are stronger—then it is difficult to account for segregation by a strictly Hebbian mechanism. According to such a mechanism, the stronger contralateral input should wrest territory from the ipsilateral inputs, which are unable to drive cells on their own. Since the contralateral inputs are stronger, earlier, there should be no opportunity for an ipsilateral input to develop. Since it clearly does, it appears that current understanding of the rules of activity-based development, based largely on Hebbian formulations involving long-term potentiation and depression (Kirkwood, Lee, and Bear, 1995; Kirkwood and Bear, 1994; Bear, Cooper, and Ebner, 1987) may not be directly applicable to the initial establishment of columns.

Once the two eyes have established the outlines of their respective territories, however, ipsilateral inputs catch up to contralateral inputs in their ability to drive cells, and the two inputs become roughly equivalent (Crair, Gillespie, and Stryker, 1998). At this point, imbalances in activity, or changes in its correlational structure, do modify cortical representations by a process that is consistent with Hebbian theories. The classic experiments of Hubel and Wiesel on the effects of eyelid closure (Hubel and Wiesel, 1970; Wiesel and Hubel, 1965a, 1965b) were done primarily during this period. Thus it is likely that the rules governing the plasticity of established (or nearly established) ocular dominance columns may be quite different from those that drive the initial formation of the segregated pattern. From this perspective, it is intriguing that Hubel and Wiesel noted that the critical period for modifying ocular dominance columns by visual experience did not begin before 3 weeks postnatal in the cat, although neurons were visually responsive and orientation selective for at least 1 week before this point. This finding suggests that the forces controlling the distribution of geniculocortical afferents are indifferent to changes in activity patterns before the geniculocortical afferents have begun segregating into stripes, a process which is well under way by 3 weeks postnatal.

Activity and the development of orientation selectivity

Neurons in the primary visual cortex are well tuned to respond to lines and bars of particular orientations. Orientation-selective neurons are grouped together into orientation columns, and, across the tangential extent of cortex, orientation selectivity is continuously repre-

sented in an orderly pattern. A substantial body of evidence supports Hubel and Wiesel's original theory (Hubel and Wiesel, 1962) for generating orientation selectivity via the summation of center-surround receptive fields of geniculocortical afferents. Although substantial sharpening of orientation tuning occurs via local cortical circuits (Douglas and Martin, 1991; Ringach, Hawken, and Shapley, 1997; Somers, Nelson, and Sui, 1995; Sompolinsky and Shapley, 1997), there is general agreement that at least a crude bias for particular orientations is formed in layer 4 by the termination patterns of geniculocortical afferents (Chapman, Zahs, and Stryker, 1991; Ferster, Chung, and Wheat, 1996; Reid and Alonso, 1995). Thus, the development of this central aspect of central visual processing architecture, like the development of ocular dominance columns, is at its heart an issue of how geniculocortical afferents acquire a specific termination pattern in layer 4.

Unlike the development of ocular dominance columns, the development of orientation selectivity has never been tightly linked to visual experience. Monkeys have fully developed orientation columns at birth (Wiesel and Hubel, 1974). Oriented neurons are present in cats immediately after eye opening, leading Hubel and Wiesel to posit that orientation tuning was a "genetically" determined property (Hubel and Wiesel, 1963). Manipulations of visual experience (such as stripe rearing) can lead to the selective preservation of certain oriented responses, but do not underlay their initial specification, nor allow respecification of a given neuron's orientation preference (Stryker et al., 1978). Moreover, even if the two eyes have completely unrelated patterns of visual experience (accomplished by alternating lid suture), the patterns of orientation maps driven by each eye are in perfect register—implying that correlated experience is not necessary for alignment (Goedde and Bonhoeffer, 1996).

Although visual experience is almost certainly not involved in creating orientation maps, the role of spontaneous neuronal activity is less clear. Silencing the cortex with pharmacological manipulations leads to an almost complete disappearance of oriented neurons (Chapman and Stryker, 1993). However, such manipulations do not distinguish between instructive and permissive roles of spontaneous neuronal activity. For example, neurons may simply need to be active to some degree in order to grow axon collaterals or to be able to read molecular signals present in the cellular environment. In this case, the amount of activity may be important, but the exact patterns less so. Conversely, if activity is instructive, then the temporal structure of patterned activity, such as the patterns of correlations between different neurons, should carry important information.

In either scenario, silencing the cortex would induce alterations. However, manipulations that alter the pattern of activity can distinguish between permissive and instructive roles: If activity is permissive, then changing the patterns, without changing levels, should have little effect, whereas if activity is instructive, changing the patterns should greatly alter the outcome. For technical reasons, there have been few attempts to alter patterns of endogenous, spontaneous activity during the relevant developmental windows.

Exogenous patterned activity and the development of orientation tuning and maps

As the preceding discussion has demonstrated, the most likely sources of spontaneous, patterned activity in the developing visual pathway are retinal waves (especially in the contralateral retina) and the thalamocortical circuits activated by them. Are such activity patterns instructive or permissive? Based on a limited number of technically challenging experiments, the answer seems to be both: Depending on the cortical layer, central disruption of retinal activity patterns has little effect on orientation tuning in layer 4, while orientation tuning outside this layer is greatly compromised.

This assertion is based on experiments in which cuff electrodes were chronically implanted around the optic nerve of neonatal ferrets (Weliky and Katz, 1997). Stimulation was applied to the entire nerve every 20 seconds for up to two weeks, beginning well before eye opening and during the period that retinal waves are still present. The idea of this paradigm was to massively synchronize the patterned activity in the visual pathway, thereby overriding any local correlations or patterns that the system might be using to set up orientation domains. Conceptually this experiment resembles strobe-rearing experiments (Cynader, Berman, and Hein, 1973; Schmidt and Buzzard, 1993), in which synchronized visually evoked activity was used to manipulate the correlational structure of activity. Using cuff stimulation, however, this could be done at a time prior to the initial establishment of orientation (and ocular dominance) columns.

The effects of massively correlating the geniculocortical input were striking. In the upper and lower layers of cortex, orientation tuning was sharply decreased compared to both normal animals and animals with cuff implants that were not stimulated (figure 13.4). Although almost all neurons showed some orientation bias, the distribution of tuning strengths in the stimulated animals was similar to that of neurons recorded from immature ferrets prior to eye opening. However, in layer 4—the site of geniculocortical afferent termination, and the presumed site where orientation selectivity is first gener-

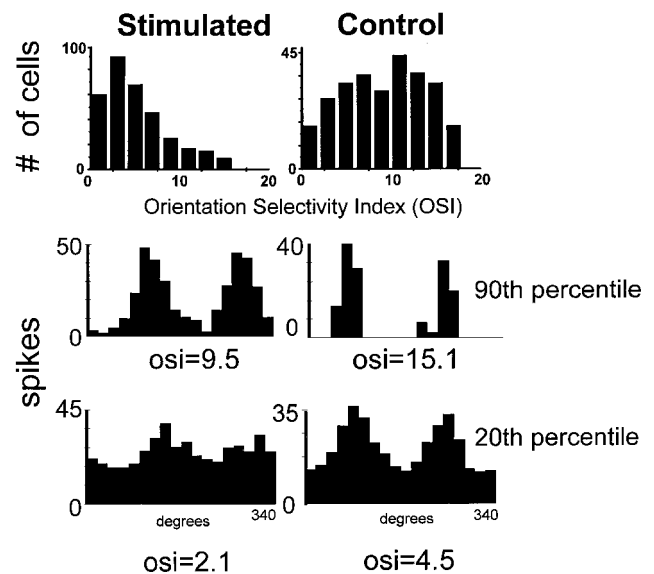

FIGURE 13.4 Effects of chronic optic nerve stimulation on orientation selectivity in ferret visual cortex. For each of several hundred neurons recorded in stimulated or control animals, an orientation selectivity index (OSI) was calculated. Stimulation resulted in a dramatic reduction in orientation selectivity, as manifested by a marked shift in orientation selectivity to lower numbers (<10). The lower four histograms show individual tuning curves to give some indication of the magnitude of this effect. Neurons in the 90th percentile of selectivity were very sharply tuned in control animals, and even cells in the 20th percentile were clearly orientation selective. In contrast, even the best tuned neurons in the stimulated animals were broadly tuned, and those in the 20th percentile were only weakly orientation selective. (Adapted from Weliky and Katz, 1997)

ated—there was no difference in orientation tuning strength (figure 13.5). In normal ferrets (and cats) cells in layer 4 have weaker orientation tuning than cells in the upper and lower layers, presumably due to contributions of intrinsic circuits outside of layer 4 to tuning. The finding that tuning in layer 4 was largely immune to large changes in the correlational structure of activity suggests that the mechanisms that initially pattern orientation tuning may differ from those that fine-tune this property.

This difference between establishment of tuning and its refinement is highlighted by another finding: In the chronically stimulated animals, the overall map of orientation selectivity is unaltered (Weliky and Katz, 1997). In normal animals, optically imaged maps of orientation selectivity show a complex pattern in which orientation selectivity changes smoothly around singularities called pinwheels (Bonhoeffer and Grinvald, 1991). In stimulated animals, the size, shape, spacing, and organization of orientation-selective domains are normal. The only difference is that the strength of orientation selectivity in any given zone is weaker than normal, reflecting the decreased tuning strength seen on a single-cell level.

FIGURE 13.5 Effects of laminar position on orientation selectivity in chronically stimulated animals. In normal animals (top histogram) the most sharply tuned neurons are located in the upper and lower layers; layer 4 neurons (roughly 700–1100 μm deep) are much less well tuned. In the stimulated cortex, all neurons exhibited roughly the orientation selectivity seen in layer 4. These results imply that chronic stimulation degraded orientation selectivity outside of layer 4 but not within layer 4, perhaps via effects on local circuits in the layers above and below layer 4. (Adapted from Weliky and Katz, 1997.)

The resistance of layer 4 orientation tuning and overall orientation maps to massive manipulations of activity can be interpreted in a number of ways. Such resistance may simply reflect the fact that manipulations that begin later in the neonatal period may simply be too late. In the case of the experiments described here, activity was altered beginning at postnatal day 25, which, although prior to the time at which orientation maps or selective cells can be seen, is still 10 days after geniculocortical afferents have arrived in layer 4. Thus it is possible that patterns of spontaneous activity at very early ages construct the initial pattern of orientation maps. Numerous theoretical models are consistent with such an assertion. However, at these later stages, activity seems to act permissively, rather than instructively, for maintaining orientation in layer 4 and the basic outline of orientation maps.

Molecular patterning and the establishment of orientation maps

Alternatively, the organization of geniculocortical afferents in layer 4 may be accomplished by entirely different mechanisms. Hubel and Wiesel actually proposed (at a time when much less was known) that orientation selectivity was genetically programmed (Hubel and

Wiesel, 1963). In more modern parlance, this suggestion would be equivalent to proposing that a set of molecular cues present in layer 4, on geniculocortical afferents, or in both could guide the initial formation of orientation maps. Is it really conceivable that a set of such cues (perhaps acting in concert with ongoing activity) could pattern a system as complex as orientation selectivity?

The molecular intricacies of pattern formation during development elsewhere in the animal kingdom make this proposal at least plausible. Extensive experimentation in butterflies has shown that the intricate patterns in this epithelial tissue can be derived by interactions among a very limited number of diffusible morphogens (Nijhout, 1991). The patterning of body segments, cell fates, and epithelial patterns in vertebrates and invertebrates, which are of sometimes startling complexity, have come to be understood as interactions between relatively small numbers of cell-surface and diffusible molecules whose distribution and timing are critical (see Lumsden and Krumlauf, 1996; Tanabe and Jessell, 1996, for recent reviews). In the nervous system, topographic mapping is determined by a small number of ligands and receptors with graded distributions in inputs and targets (Cheng et al., 1995). And perhaps most strikingly, the extraordinarily specific connections between the olfactory epithelium and the olfactory bulb rely on perhaps hundreds of distinct molecular cues that guide spatially scattered receptors to terminate within a single glomerulus (Wang et al., 1998). Neuronal activity appears unimportant in this system (Belluscio et al., 1998). Thus the complexity of the orientation map alone is not a sufficient argument for discarding a molecular mapping strategy. Virtually all experimental approaches to date have manipulated activity, and there has been little effort to design experiments to reveal possible molecular cues that this system could use. If such cues are indeed present, it is likely that they will be transient and present at very early times in development, perhaps when geniculocortical afferents are still arriving.

Activity and the development of ocular dominance columns: A reconsideration

Earlier in this chapter a clear distinction was made between the initial establishment of ocular dominance columns and their subsequent plasticity. Though a long tradition of experimental evidence supports the notion that activity plays an instructive role in ocular dominance plasticity (Chapman et al., 1986; Gu, Bear, and Singer, 1989; Kleinschmidt, Bear, and Singer, 1987; Reiter, Waitzman, and Stryker, 1986; Stryker and Harris, 1986; Wiesel and Hubel, 1965b), much less is known about activity's roles during their initial establishment. The issue of distinguishing instructive ver-

FIGURE 13.6 Segregation of geniculocortical axons into columns in the absence of the eyes. In an animal enucleated at postnatal day 15 (just after thalamic afferents have arrived in layer 4) and allowed to survive until postnatal day 70, injection of an anterograde tracer into one layer of the LGN reveals clearly segregated patches of terminals in layer 4 of visual cortex. These patches have a center-to-center spacing of

about 500 μm , indistinguishable from the patches seen in normal animals. Thus thalamic afferents can segregate without any input from the retina, suggesting that cues present in the thalamus, cortex, or both are sufficient to establish segregated columns. (From J. C. Crowley and L. C. Katz, unpublished results.)

sus permissive roles of activity has been discussed, and the same arguments hold for examining ocular dominance columns. Simply silencing either the retina or the cortex implicates neuronal activity in the development of these connections, but such a manipulation cannot determine whether activity patterns are important and, by implication, whether Hebbian or other correlation-based mechanisms are at work.

The results of recordings in neonatal ferret thalamus provided an intriguing hint of an experimental approach for specifically manipulating correlational patterns without significantly disrupting activity levels in the developing visual system. Recall that when both optic nerves were severed in a neonatal ferret, a new pattern of spontaneous activity emerged, driven by the thalamocortical loop (figure 13.3) (Weliky and Katz, 1998). The result of severing the optic nerves was a dramatic increase in correlation of activity in the two eye-specific layers. Thus, in contrast to normal animals, in which the correlations between eye-specific layers were relatively low, in enucleated animals the correlations between the two LGN layers were much higher.

Under such circumstances, can geniculocortical afferents still segregate into eye-specific stripes—the equivalent of ocular dominance columns? Remarkably, they can. Both anterograde and retrograde tracing experiments reveal that in animals binocularly enucleated at P15 (just after geniculocortical afferents have reached layer 4) and examined at P70 (after the close of the criti-

cal period) geniculocortical afferents segregate into eye-specific zones with a periodicity and precision indistinguishable from normal control animals (figure 13.6) (J. C. Crowley and L. C. Katz, unpublished results).

One obvious implication of such a finding is that continuous presence of patterns of activity originating from the retina, whether spontaneous or evoked, are not required for segregation of geniculocortical afferents. What is critical, however, is that removing the eyes is not equivalent to silencing the remaining portions of the visual pathway: *In vivo* recordings amply demonstrate that enucleation induces a new pattern of spontaneous activity whose correlational structure is very different from normal. In contrast, binocular injections of tetrodotoxin completely silence the thalamus and cortex (Stryker and Harris, 1986). In this case, the silencing of the system prevents or delays emergence of ocular dominance columns. Although it is certainly possible that the patterns of activity in the enucleated animals retain sufficient correlational structure to allow afferents to segregate using Hebbian mechanisms, another interpretation is that neurons must simply be active in a specific pattern in order to express or access molecular cues.

Many features of cortical architecture appear to emerge in enucleated animals. In primates, early enucleation does not prevent normal synaptogenesis (Bourgeois and Rakic, 1996), the differentiation of cortical layers, the laminar-specific organization of monoaminergic receptor systems (Rakic and Lidow, 1995),

or the appearance of cytochrome oxidase blobs (Kuljis and Rakic, 1990). In the experiments in ferrets described earlier, enucleation also did not prevent appearance of clustered horizontal connections in the upper layers of striate cortex (J. C. Crowley and L. C. Katz, unpublished observations). Similar experiments (Ruthazer and Stryker, 1996) done at somewhat later ages showed similar results. In normal adult animals, such clusters link orientation columns that share orientation preference. The fact that clustered connections can emerge entirely independent of retinal activity, and in the presence of highly correlated thalamic activity, further strengthens the idea that the circuitry involved in orientation tuning may also develop without reference to correlation-based cues.

Investigations in a number of systems, including developing neurons, have shown that periodic patterns of activity produce distinct patterns of intracellular calcium fluxes that in themselves determine patterns of gene expression. This relationship has been clearly shown in developing *Xenopus* spinal cord neurons. Different frequencies of calcium-mediated events—"spikes" versus "waves"—regulate distinct aspects of neuronal differentiation (Gu and Spitzer, 1995). For example, calcium waves appeared to regulate neurite extension, whereas spikes mediated changes in excitability and transmitter expression. In fact, periodic bursts of activity are a ubiquitous feature of neuronal development: Not only are waves present during the development of the retina in all vertebrate species examined thus far (including ferrets, mice, chickens, and turtles), but oscillations with similar properties are also present in the developing spinal cord (Ho and O'Donovan, 1993; O'Donovan, 1989), cortex (Yuste, Peinado, and Katz, 1992), and substantia nigra (Christie, Williams, and North, 1989). In systems like the substantia nigra there is little reason to suspect that the correlational structure of activity is critical, implying that such periodic bursts are critical to the differentiation of the neurons, rather than for providing a substrate for Hebbian segregation (Gu and Spitzer, 1997; Spitzer, Olson, and Gu, 1995).

In the specific context of normal ocular dominance column development, then, one can imagine retinal waves and the patterned downstream activity they induce as having at least two potential roles. The first is the conventional view in this field, namely that the specifics of pre- and postsynaptic correlation patterns critically determine the development of specific patterns of connections. An alternative, albeit extreme, view is that patterns of activity are critical for inducing specific patterns of gene expression and cell differentiation, but that the details of correlations between cells are not carrying instructive information. In this view, bursting in a given

cell is critical for activating important genetic programs, but whether a cell is bursting in concert with neighbors in the same or different layers is irrelevant. Thus, in animals with no eyes, even though correlations between layers are high, all cells are undergoing periodic intracellular calcium fluxes, which enable them to express and decode cues necessary for ocular dominance column formation.

The NMDA receptor may play a critical role in modulating these calcium fluxes. Early in cortical development, this receptor appears to be the dominant glutamate receptor, and the voltage-dependent magnesium block appears to be considerably weaker. Thus, the NMDA receptor may function less as a correlation detector and more as a conduit for periodic calcium fluxes. Blocking this receptor could therefore inhibit initial column formation not by blocking correlated activity per se, but by blocking the calcium oscillations necessary to elicit expression or detection of specific molecular cues. Thus the failure of columns to form in the complete absence of activity can be interpreted not as an elimination of correlations, but as an elimination of this critical permissive cue.

Of course, this view is based on a very limited number of experimental findings. And there are certain observations that flatly contradict the notion that molecular cues are required for segregation of functionally distinct groups of axons. The most compelling of these comes from experiments in three-eyed frogs. In this system, when retinotectal axons from two eyes are forced to innervate a single optic tectum, they segregate in an activity-dependent (and NMDA-receptor-dependent) fashion. The frog optic tectum is normally innervated exclusively by the contralateral retina, so it is absurd to propose that there exists some stripelike endogenous cue for either of the two eyes. However, the fact that correlated activity in frogs *can* induce stripe formation does not mean that the identical mechanism *must* be responsible in the cortex of mammals. Stripes in epithelial structures (and neurons are epithelial in origin) are a general solution to many different biological constraints, and the finding of correlation-based stripes in the frog optic tectum does not prove that stripes in striate cortex have the same mechanistic underpinnings.

The finding of a contralateral bias also indirectly strengthens the notion that molecular cues may be involved. Why do stronger contralateral inputs not take over the inactive areas that later are dominated by ipsilateral inputs? Perhaps some patterned cell surface cue specific to contralaterally derived axons prevents ingrowth. Contralateral inputs are derived from the nasal part of the retina, and the demarcation between nasal and temporal retina is set up very early in development

and is almost certainly determined by intrinsic molecular cues. It is not too difficult to imagine that the cues that distinguish nasal and temporal retina can be utilized throughout the visual pathway. Guidance molecules, such as the semaphorins, exist in many different varieties, and have been shown to distinguish between closely related axons in a variety of brain structures (Goodman, 1994). Indeed there are suggestions that even at the level of the LGN, there exist intrinsic molecular cues that can pattern the terminal arbors of retinal axons (Miessirel et al., 1997; Sretavan and Shatz, 1986a).

Molecular signals for cortical functional architecture

For many years, the emphasis of research on the development of cortical architecture has been heavily influenced by the finding that correlation-based, long-term changes in synaptic efficacy, such as LTP and LTD, can be elicited in the developing (and mature) thalamus and visual cortex (Bear, 1995; Bear and Kirkwood, 1993; Bear and Malenka, 1994; Kirkwood and Bear, 1994; Kirkwood, Lee, and Bear, 1995; Mooney, Madison, and Shatz, 1993). Most work has been premised on the belief that such alterations must be largely responsible for structural plasticity in this system. Far less attention has been devoted to the possibility that molecular maps may in some way prefigure the eventual architecture of visual cortex.

Nevertheless, there have been occasional intriguing reports of molecular patterns that are present before architecture is fully formed. For example, in the developing cat visual cortex, specific classes of serotonin receptors form striking, periodic columns with the center-to-center spacing of ocular dominance columns (Dyck and Cynader, 1993b). Such periodicity is difficult to reconcile with the accepted wisdom (required for most correlation-based models of ocular dominance column formation) that all the territory in layer 4 (along with the inputs from the two eye-specific geniculate layers) is functionally equivalent. Zinc (associated with synaptic terminals), cytochrome oxidase (a metabolic marker), and acetylcholinesterase are also distributed in complex, frequently interdigitating patterns (Dyck, Beaulieu, and Cynader, 1993; Dyck and Cynader, 1993a). As early as 2 weeks postnatal, Trepel and colleagues (1998) observed a nonuniform distribution of the NMDA-receptor-immunoreactive neurons, suggesting that certain loci in the early developing cortex are more susceptible to modification by activity.

However, most of these molecules are likely to be downstream of even earlier signals. Neurons in the developing cortex acquire their laminar identity while still in the ventricular zone (McConnell, 1988). In ferrets,

layer 4 neurons reach the cortical plate around postnatal day 10 and geniculocortical afferents arrive soon after (Jackson, Peduzzi, and Hickey, 1989). Cues may also be present in the developing subplate, an early-generated population of neurons that receive a transient connection from the thalamus. Ablation of this population prevents ocular dominance column formation (Ghosh and Shatz, 1994), so it is conceivable that the markers distinguishing ipsilateral and contralateral inputs from the LGN could be present soon after the very first cells of the cortex are postmitotic. There has been little effort—and, until recently, little motivation—to examine whether guidance molecules are inhomogeneously distributed in the cortical plate at such early stages.

Another possible source of cues resides in the retina. There is clear evidence that at least some of the functional segregation that occurs in the developing LGN is based on molecular distinctions and not activity alone. For example, M and P pathways in the primate emerge without significant overlap in the LGN, and this distinction appears to emerge as soon as the respective retinal ganglion cells complete their last division (Miessirel et al., 1997). As discussed previously, retinal ganglion cells in nasal and temporal retina are almost certainly molecularly distinct, and these are the sources of the ipsilateral and contralateral inputs to the LGN. Using modern molecular techniques such as subtraction or differential display, it may be possible to get some hints about the signaling pathways involved in distinguishing these two pathways beginning at the retina.

Conclusions

The currently accepted view of the development of cortical architecture relies heavily on correlation-based mechanisms involving the NMDA receptor and phenomena such as LTP and LTD. While there is little question that activity at some level is crucial for the plasticity of cortical connections, there is a small but growing body of evidence that the initial establishment of cortical architecture may utilize activity in a very different context. Moreover, by analogy with other developing systems, there are reasons to suspect that as-yet-undiscovered molecular cues may frame the detailed connectivity of the developing visual system. Rather than designing more experiments to ratify the existing dogma of correlation-dependent mechanisms, it may be time to design approaches to determine whether such molecular cues indeed exist.

14 Development of Neural Maps: Molecular Mechanisms

RENPING ZHOU AND IRA B. BLACK

ABSTRACT Neural circuits, the structural basis of cognition, are organized in a highly ordered fashion. The spatial order of neurons is often preserved by their axonal termini in target tissues, forming topographic projection maps. During the development of these maps, axons are guided by multiple mechanisms to travel long distances to specific targets. The guidance cues can be attractive or repulsive, and can be diffusible or membrane bound. Among the many guidance molecules, two families have emerged as key factors regulating topographic map formation: they are tyrosine-kinase-family receptors and ligands, and cell adhesion molecules. In the tyrosine kinase family, neurotrophins are candidates for attractive cues, while the Eph subfamily receptors and ligands are repulsive/inhibitory cues. The specificity of maps comes from the graded distribution of the Eph receptors and ligands in the pre- and postsynaptic fields, and negative effects for axonal growth are generated from the ligand-receptor interactions. Properly distributed axon termini may be stabilized by cell adhesion molecules expressed in both the projecting and target neurons through homophilic interactions. Thus the concerted actions of multiple guidance molecules are necessary for the construction of topographic maps during development.

The concept that sensory information is encoded in the brain as topographic maps, which reflect the external world and morphology of sensory organs, has existed since the time of Descartes (1644, 1647). Such topographic encoding is critical for brain functions, as evidenced by orderly representations of sensory surfaces and body effectors in the sensory and motor systems and by experience-dependent plastic changes of these representations (Kaas, 1991). Recent studies using modern histological and tracing techniques have demonstrated that topographic mapping is a basic principle of brain architecture. Neuronal inputs to the central nervous system (CNS) are topographic in many sensory systems including the visual, the auditory, and the somatosensory projections (reviewed in Udin and Fawcett, 1988). Topographic maps are not restricted to sensory

systems. They also exist in the limbic circuits that mediate learning, memory, and emotions. One of the major limbic components, the hippocampus, for example, is connected to its subcortical target, the septum, in a highly organized manner (Swanson, Kohler, and Bjorklund, 1987). Similarity in organizing principles between limbic circuits and sensory systems suggests that learning, memory, and emotions are governed by the same spatial constraints as sensory information processing.

There are at least four stages in the development of topographic neural maps. First, appropriate phenotypic fates must be determined for projecting and target neurons so that specific cognitive surface tags are expressed at proper concentrations by neurons spatially and temporally. Second, axons must navigate appropriate paths to reach their targets. Third, terminals must be guided to proper topographic locations after arriving at the projection targets. Fourth, gross topographic maps must be refined to generate precise functional maps. Very little is known about the initial differentiation of projecting and target fields that express specific guidance tags. In contrast, considerable knowledge has recently been obtained regarding axonal navigation to targets (Tessier-Levigne and Goodman, 1996; Goodman, 1996). This chapter focuses primarily on recent advances elucidating how guidance cues direct axon terminals to proper locations to establish coarse maps. We initially discuss mechanisms for topographic mapping, and then examine the molecular identity of guidance cues. Finally, the concerted actions of various cues in two model systems are presented to demonstrate how neural maps are constructed. Mechanisms for refinement of maps have recently been reviewed by Goodman and Shatz (1993) and will not be discussed here.

Guidance mechanisms

Given the central importance of neural maps in cognition, developmental mechanisms have attracted much attention for over half a century. Several models have been proposed. It was widely believed in the 1930s and 1940s that axons were guided primarily by mechanical

RENPING ZHOU Department of Chemical Biology, College of Pharmacy, Rutgers University, and Department of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, Piscataway, N.J.

IRA B. BLACK Department of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, Piscataway, N.J.

patterns in the tissues (Weiss, 1939; Weiss and Taylor, 1944). This hypothesis proposed that axons were oriented by mechanical stresses within the tissue ultrastructure and grew along physical guidelines in the developing tissues. The critical prediction of this hypothesis—that axons growing into the target through different paths would not be able to form proper maps—was refuted by later experimental observations. In salamanders, retinal axons traveled by completely anomalous routes to form correctly ordered retinotectal projections (Harris, 1982). Consequently, the proper positioning of axonal terminals did not rely on the route of growth, but rather was determined by other mechanisms such as addresses in the tectum.

CHEMOAFFINITY THEORY At the end of the 19th century, Cajal and others proposed that axons might be guided by chemical attraction or trophic mechanisms (Ramon y Cajal, 1893). This proposal was later developed into the chemoaffinity hypothesis by Roger Sperry based on studies of retinotectal projections (Sperry, 1963). Retinal ganglion cells project to the tectum, a visual center in the brain, in a highly ordered manner (Sperry, 1963; Gaze, Jacobson, and Szekely, 1963). The observation that the target positions of retinal ganglion axons were determined strictly by their embryonic spatial origin led Sperry to reject the mechanical theory of axonal guidance. Regenerating axons from different parts of the retina made connections with specific predestinated target zones in the tectum. These axons grew across large sections of nontarget tectal zones without forming synapses. Furthermore, retinal axons traveled through abnormal routes generated by artificial displacement to reach their embryonically defined targets, suggesting that the cells had intrinsic guidance tags and did not rely on physical guidance mechanisms (Sperry, 1944). In one experiment, Sperry rotated the eyes 180° and showed that the regenerating retinal axons still made appropriate connections according to their original locations. These animals also had functional vision, except that their visual world was inverted and reversed. The visual inversion was never corrected by experience, suggesting that learning did not play major roles in the establishment of terminal organization of retinal axons. These observations contradicted the contention that maps were organized by functional selection, a popular concept early in the 20th century (Jacobson, 1991).

These studies lead to the chemoaffinity hypothesis, holding that axons are guided to proper targets by matching cytochemical tags on presynaptic and postsynaptic neurons (Sperry, 1963). Sperry further proposed that the tags might be distributed in the projecting and target fields in gradients, and that only *quantitatively*

matching concentrations of the *complementary tags* allowed synapse formation. Such tag pairs might be oriented along perpendicular axes to define multidimensional maps. The chemoaffinity theory has been supported by numerous developmental, electrophysiological, and molecular studies, and candidate molecular tags have been recently identified.

MULTIPLE MECHANISMS Sperry's chemoaffinity theory emphasized the critical importance of chemical affinity, implying attractive interactions between axons and targets with matching guidance tags. Recent studies have identified at least four different guidance mechanisms that direct axons to proper targets (reviewed in Goodman, 1996, and Tessier-Levine and Goodman, 1996). They include diffusible and contact-mediated positive and negative guidance. For the development of topographic neural maps, two additional guidance mechanisms, axonal elimination and activity-dependent refinement, are also involved.

Over a century ago, Ramon y Cajal (1893) first suspected the existence of diffusible chemoattractants released by the targets to guide distant incoming axons. Recent analyses have identified several chemoattractants (Goodman, 1996; Tessier-Levine and Goodman, 1996). Axons are specifically attracted toward targets by these factors. Growth cone behavior is also influenced by contact-mediated attractive molecules, such as growth-promoting cell adhesion molecules (CAMs). These positive signals may function either by attracting growth cones or by supporting survival of growing axons.

In vitro assays that examine the effect of guidance cues on growth cone extension revealed several diffusible, repulsive signals (Dodd and Schuchardt, 1995; Keynes and Cook, 1995; Goodman, 1996; Tessier-Levine and Goodman, 1996). Axons grow away from the source of these signals. Similar to the positive guidance cues, negative regulation of axons can also be contact mediated. Bonhoeffer and colleagues elegantly demonstrated that a gradient of contact repulsive signals exists in the visual tectum that specifically repels temporal retinal axons (Walter, Muller, and Bonhoeffer, 1990).

Axons or neurons projecting to improper spatial locations may be eliminated. In rodents, retinal axons initially project to the superior colliculus with little topographic specificity (Simon and O'Leary, 1990, 1992; Nakamura and O'Leary, 1989). Excess axons or branches are removed only later (Simon and O'Leary, 1990, 1992; Nakamura and O'Leary, 1989). In the chicken, refinement of the retinotectal map also occurs by eliminating entire ganglion cells with targeting errors (Rager and Rager, 1978; Hughes and McLoon, 1979). Further refinement of the coarse topographic maps can

be achieved by neuronal electrical activity (Goodman and Shatz, 1993).

Molecular identity of topographic mapping cues

Given the importance of neural maps, a major effort in modern neurobiology has been directed to the identification of axonal guidance molecules. The candidates identified so far belong to several distinct families. However, they share a common property: Their signaling components all contain ligands and receptors expressed in the presynaptic and postsynaptic fields. We focus on molecules with clearly demonstrated guidance functions in map formation. They include members of the receptor-tyrosine-kinase family (which phosphorylates proteins on tyrosine) and the cell-adhesion-molecule (CAM) family.

RECEPTOR TYROSINE KINASES AND THEIR LIGANDS

Receptor tyrosine kinases, key components in the transduction of extracellular signals across the cell membrane, play critical roles in neuronal growth, survival, and axonal guidance. Numerous receptor kinases have been characterized and typically exhibit an extracellular ligand-binding domain, a transmembrane region, and an intracellular kinase domain (van der Geer, Hunter, and Lindberg, 1994). Upon ligand binding, the kinase is activated and modifies other intracellular signaling proteins. During the development of neural maps, this ability to respond to extracellular signals allows incoming axons to recognize target neurons.

The tyrosine kinase receptors are classified into many different subfamilies according to sequence homology. Members of each subfamily share a higher degree of homology with each other than with members from other families. Although the kinase domains are well conserved, the extracellular domains have diverged among different receptors. The extracellular domains are typically composed of a number of different structural domains such as the IgG-like and the fibronectin type III-like regions (van der Geer, Hunter, and Lindberg, 1994). Members of each receptor subfamily have distinct topological organization of these structure domains (van der Geer, Hunter, and Lindberg, 1994). The unique sequences of the ligand-binding domains allow specific interaction with distinct ligands and consequent diverse responses by neurons to different guidance or survival cues.

The Eph subfamily receptors and ligands The Eph subfamily receptors and ligands have emerged recently as major players in the development of topographic neural maps (Brambilla and Klein, 1995; Tessier-Lavigne,

1995; Friedman and O'Leary, 1996; Pandey, Lindberg, and Dixit, 1995; Orike and Pini, 1996; Muller, Bonhoeffer, and Drescher, 1996; Zhou, 1998). The Eph subfamily is the largest known group of receptors, consisting of at least 14 distinct members. For many years, study of Eph receptor function was hampered by the lack of identified ligands. However, the recent isolation of at least eight distinct ligands (the ephrins) has helped elucidate potential roles of the receptors in many developmental processes, including axon guidance and the formation of topographic projection maps (Zhou, 1998).

The Eph ligands are unique. They are all membrane anchored, either by a glycosylphosphatidylinositol (GPI) linkage or a transmembrane domain. Furthermore, membrane attachment is required for function. Soluble ligands fail to activate the receptors, in contrast to ligands of many other members of the tyrosine-kinase-receptor subfamily. The association with membranes restricts diffusion and confines the Eph ligands to specific spatial locations. Thus the ligands and receptors of this subfamily are uniquely suited for guiding axons to specific targets.

Recent in vitro and in vivo studies indicated that the Eph subfamily receptors and ligands play critical roles at multiple stages of map development. These roles include guiding axons along proper tracks toward the target tissues, axon fasciculation, and topographic mapping of axon termini in the target field (reviewed in Zhou, 1998).

Trophic factors and their receptors Positive guidance cues also appear to be required in developing topographic maps (Boxberg, Deiss, and Schwarz, 1993). Trophic factors are prime candidates for this role. It has been proposed that these factors, supplied in limiting amounts by target tissues, regulate neuronal connectivity by supporting the survival of appropriate axons while eliminating mistargeted or excess axons and/or neurons (Purves, 1988). Trophic factors belong to a variety of different molecular families. Factors in the neurotrophin subfamily, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 and -4, interact with the trk subfamily tyrosine kinase receptors, as well as a low-affinity receptor, p75 (Chao, 1992; Barbacid, 1995; Bothwell, 1995). The glial cell-derived neurotrophic factor (GDNF) family of trophic factors interact with cell surface coreceptors and the tyrosine kinase receptor Ret. Binding to the coreceptors is necessary before interacting with the signaling receptor Ret (Olson, 1997; Robertson and Mason, 1997). Other neurotrophic factors include fibroblast growth factor (FGF) and the cytokine ciliary neurotrophic factor (CNTF), which are ligands of tyrosine kinase receptors and cytokine receptors, respectively. These neurotrophic factors support the survival of

a variety of different neuronal populations and often have partially overlapping activities (Korsching, 1993). Recent studies indicate that neurotrophic factors serve as target-derived positive regulators that attract and stabilize incoming axons (Davies, 1996). A number of neurotrophic factors are found in the peripheral or central target tissues, while their receptors are expressed in the projecting neurons (Davies, 1996), suggesting critical roles in the development of neural maps.

CELL ADHESION MOLECULES Studies of the cell adhesion molecules indicate that they may participate in the elaboration of maps. There are large numbers of CAMs, and they belong to several gene families, including the immunoglobulin superfamily and cadherins. The roles of CAMs in neurodevelopment have been investigated intensively using several different approaches. Expression analyses revealed that many CAMs have specific patterns of expression *in vivo*. Some showed expression in discrete sets of nuclei that constitute functional neural circuits (Levitt, 1984; Reinoso, Pimenta, and Levitt, 1996; Redies and Takeichi, 1996; Takeichi, 1995). Culture studies indicated that CAMs generally promote axonal growth and may function *in vivo* to guide growth cones through contact-mediated attractions (Walsh and Doherty, 1997), although exceptions, such as myelin-associated glycoprotein and connectin, function as contact-mediated repulsive cues (Mukhopadhyay et al., 1994; McKerracher et al., 1994; Nose, Takeichi, and Goodman, 1994). Different CAMs show specific ability to promote neurite growth of specific neurons (Pimenta et al., 1995). Antibody perturbation experiments and genetic analyses showed that inhibition of CAM function leads to targeting errors in a variety of neural circuits. Several CAM molecules have been implicated in neural map formation. They include the limbic system-associated membrane protein (LAMP) (Zhukareva and Levitt, 1995; Pimenta et al., 1995), neural cell adhesion molecule (NCAM) (Walsh and Doherty, 1997), and cadherins (Takeichi, 1995; Ranscht, 1994).

Development of topographic neural maps in the brain

The development of topographic maps *in vivo* is likely to be guided by combinations of different guidance mechanisms. The Eph subfamily ligand/receptor interaction is well recognized to provide negative guidance. Although other guidance interactions remain to be characterized, several classes of molecules including CAMs and GDNF-related factors appear to serve as positive guidance cues. In this section we discuss two different topographic systems, the hippocamposeptal and the ret-

inotectal maps, to demonstrate how the concerted actions of different guidance mechanisms help to establish topographic neuronal connections.

HIPPOCAMPOSEPTAL MAP The hippocampus is critical in spatial learning and memory (Zola-Morgan and Squire, 1993), functions that depend on complex topographic connections to a number of related structures (Swanson, Kohler, and Bjorklund, 1987; Lopes da Silva et al., 1990). The hippocampus receives projections from the entorhinal cortex, which receives multimodal input from a wide variety of cortical regions. The entorhinal projection to the hippocampus innervates dentate granule cells, which in turn project to area CA3 through the mossy fibers. The CA3 pyramidal cells project to the CA1 region via Schaffer collaterals, forming a trisynaptic circuit within the hippocampus. The hippocampal efferents are sent to two major forebrain locations. One projection reaches broad parts of the cerebral cortex and influences the long-term storage of memories. The other projection is directed toward the septum (Risold and Swanson, 1996; Swanson and Cowan, 1977), which plays critical roles in modulating hippocampal activity. The connections from the entorhinal cortex to the hippocampus to the lateral septum are arranged topographically, suggesting that ordered projections are crucial for hippocampal cognitive function.

Among the hippocampal circuits, the hippocamposeptal map serves as a useful model system. The ingrowth of hippocampal axons to the septum occurs from embryonic day 21 (E21) to postnatal day 14 (P14) in the rat (Linke, Pabst, and Frotscher, 1995). Although it is not known how the axons are guided through the fornix and fimbria to reach the septal target, LAMP appears to serve as a contact-mediated positive guidance cue for the incoming axons. High levels of LAMP were detected in both the hippocampal neurons and the septal target (Pimenta et al., 1995; Reinoso, Pimenta, and Levitt, 1996). Consistent with this notion, LAMP promotes the growth of hippocampal axons and mediates homophilic binding (Pimenta et al., 1995; Zhukareva and Levitt, 1995).

Hippocampal axons terminate primarily in the lateral portion of the septum. Axons from the medial hippocampus project mostly to the dorsomedial region of the lateral septum, whereas axons from the lateral hippocampus terminate in the ventrolateral target (figure 14.1; see color plate 5). Thus neurons project along the mediolateral axis of the hippocampus to the dorsomedial-to-ventrolateral axis of the septal target. Although LAMP may be important in stabilizing interactions between the connections of hippocampal and septal neu-

FIGURE 14.1 Regulation of topographic map formation in the hippocamposeptal projection. Medial (M) hippocampal neurons send their axons to the dorsomedial (DM) septal target, while the lateral (L) hippocampal neurons target the ventrolateral (VL) septum. The ligands located in the ventral lateral septum serve to restrict the medial hippocampal neurons (Eph receptor-positive, red) from innervating this region (ligand-positive, blue), which is topographically inappropriate for the medial neurons. However, the ligands allow the innervation of the ventral lateral septum by the lateral hippocampal neurons, because they express few Eph receptors (yellow). In addition to the Eph subfamily receptors and ligands, the GDNF receptor Ret is expressed in the hippocampal neurons, while the ligand-binding coreceptors GFR α 1 and 2 are transcribed in the septum. The coreceptors are likely to trap GDNF and/or neurturin and thus serve as target-derived trophic factors for incoming hippocampal axons. Furthermore, both the hippocampal and the target neurons express LAMP, a homophilic cell adhesion molecule, which may serve to stabilize the connection between hippocampal axon terminals and the septal target cells.

rons, the uniform distribution of LAMP indicates that it is unlikely to be responsible for differential topographic mapping of hippocampal axons.

Topographic mapping appears to be regulated by the Eph subfamily ligands and receptors (figure 14.1; see color plate 5). Inhibitory interactions between Eph receptors and ligands that are expressed in gradients in the pre- and postsynaptic neurons are responsible for mapping axon termini with increasing concentrations of receptors over target areas with decreasing amounts of ligands. Analysis of expression of the Eph subfamily receptors showed that several members including EphA3, A5, A6, and A7 are expressed in the hippocampus in lateral (low)-to-medial (high) gradients (Gao et al., 1996; Y. Yue and R. Zhou, unpublished results). Opposing to the gradients of the receptors, at least three ligands, ephrin-A2, A3, and A5, are expressed in the subcortical target of hippocampus, the lateral septum. All three ligands show dorsal (low)-to-ventral (high) expression gradients. However, there are some differences in the spatial distribution of these ligands. Ephrin-A2 and A3 are transcribed in narrow stripes along the lateral edge of the lateral septum, whereas ephrin-A5 appears as diffused signals in the ventral lateral septum

(Zhang et al., 1996). Combination of all three ligands forms a continuous dorsomedial-to-ventrolateral gradient. The septal ligand gradient is complementary (opposing) to the receptor gradient. Hippocampal neurons that express high levels of receptors (medial hippocampus) project to target areas where low levels of ligands are transcribed (dorsal target). Conversely, hippocampal neurons that express low levels of receptors (lateral hippocampus) send axons to the target region with high ligand expression (the ventrolateral target). Thus the gradients of receptor and ligand expression in the projecting and target fields fulfill the requirement of chemoaffinity theory and suggest a function in neuronal mapping.

The countergradients predict that the ligands are repulsive or inhibitory for receptor-positive hippocampal axons. The biological effects of the three ligands on hippocampal neurons were tested using a coculture assay in which medial or lateral hippocampal neurons were cocultured with ligand-expressing cells. All three ligands showed an ability to differentiate the medial versus lateral hippocampal neurons. The growth of neurites from the medial, but not the lateral, hippocampal neurons was specifically inhibited by the ligands (Gao et al., 1996; P.-P. Gao and R. Zhou, unpublished data). Consistent with the inhibition, ephrin-A5 caused growth cone collapse of both the hippocampal and the cortical neurons (Meima et al., 1997). Thus axons with increasingly higher levels of receptor expression are likely to terminate over the septal target with decreasing levels of ligand expression. Once the termini are distributed through selective inhibition via Eph ligand/receptor interaction, homophilic interaction between LAMP expressed in both in the pre- and postsynaptic neurons is likely to stabilize the projection. These observations indicate that the hippocamposeptal map is directed by a combination of positive and negative guidance interactions between the pre- and postsynaptic neurons (figure 14.1; see color plate 5).

RETINOTECTAL MAP Studies of the retinotectal projections, as a model system for neural map development, have been informative in our understanding of the molecular mechanisms (Roskies, Friedman, and O'Leary, 1995). The projection of retinal ganglion cell axons to the tectum is highly organized: Temporal axons terminate in the anterior tectum, and nasal axons map to the posterior tectum (figure 14.2; see color plate 6). To elucidate the nature of guidance cues, Bonhoeffer and colleagues examined the ability of retinal ganglion axons to discriminate between the anterior and posterior tectal target in vitro (Bonhoeffer and Huf, 1985). They observed that temporal retinal axons

FIGURE 14.2 Specification of retinotectal topographic map. Temporal and nasal retinal ganglion neurons project to the anterior and posterior portions of the chick tectum (superior colliculus in mammals), respectively. The Eph receptor EphA3 is expressed in a nasal (N, low)–to–temporal (T, high) gradient in the retina. The Eph ligands ephrin-A2 and A5 are expressed in the tectum in an anterior (A, low)–to–posterior (P, high) gradient. The ligand gradient serves to repel/eliminate receptor-positive temporal axons. The extent of inhibition may be proportional to the extent of ligand–receptor interaction. In contrast, GDNF entrapped by its binding receptor GFR α s and BDNF may serve as a positive guidance cue to promote the ingrowth of retinal axons in general.

prefer to grow on membrane extracts from the anterior tectum, their topographically correct target, but are repelled by the posterior extracts (Stahl et al., 1990). The selectivity is due to repulsive cues in the posterior target. To identify the negative guidance cue enriched in the posterior tectum, Drescher and colleagues (1995) isolated a 25 kD membrane protein using two-dimensional gel electrophoresis, which they initially named repulsive axon guidance signal, or RAGS. The RAGS protein is distributed in an anterior-to-posterior gradient in the tectum and has stronger repulsion for the temporal axons than the nasal axons in vitro (Monschau et al., 1997). The graded distribution and repulsive activity against the retinal axons indicate that RAGS is a candidate guidance cue and potentially plays a key role in the establishment of retinotectal topographic map.

Sequence analysis revealed that RAGS is the chicken homologue of ephrin-A5, a ligand of the Eph subfamily (Winslow et al., 1995; Drescher et al., 1995). In vivo analysis using gene knockout technique confirmed a critical role of ephrin-A5 in retinotectal topographic map formation (Frisen et al., 1998). Independently, studies by Flanagan and colleagues implicated a different ligand of the Eph subfamily, ephrin-A2, in the guidance of retinal axons (Cheng et al., 1995; Nakamoto et al., 1996). Ephrin-A2 is expressed in an anterior-to-posterior gradient in the tectum and repels the temporal but not the nasal axons in vitro. Counter to the ligand

expression in the tectum, the receptor of ephrin-A2 and A5, EphA3 is distributed in a nasal (low)–to–temporal (high) gradient in the retina. The existence of opposing ligand–receptor gradients in both the retinotectal and hippocamposeptal systems indicates that these molecules use similar mechanisms in specifying different maps in the brain.

To demonstrate a guidance role in vivo, ephrin-A2 was expressed ectopically in the tectum using a retroviral vector (Nakamoto et al., 1996). The temporal axons avoided areas of ectopic ephrin-A2 expression and mapped to abnormally anterior positions, whereas no effect was observed on the nasal axons. These observations provide direct evidence that ephrin-A2 is a guidance molecule that determines target specificity of the temporal axons by inhibiting axon growth through a countergradient of receptors in the presynaptic terminals (figure 14.2; see color plate 6). Together with their function in the hippocamposeptal projection, these findings demonstrate that the Eph receptors and ligands are universal negative regulators in establishing topographic maps.

The cellular mechanisms underlying ephrin function have not been well characterized. Earlier studies indicate that retinal ganglion axons initially explore and project to much broader areas than the final targets (Nakamura and O’Leary, 1989; Simon and O’Leary, 1990, 1992). In rodents, both nasal and temporal axons extend through the entire superior colliculus during early development (Simon and O’Leary, 1990, 1992). However, mistargeted axons are later pruned (Simon and O’Leary, 1990, 1992). We have shown that ephrins have dual effects on hippocampal axons in vitro, initially stimulating axonal extension and branching, but subsequently causing degeneration (unpublished observations). Consequently, ephrins may determine topographic positions by axonal elimination, in contrast to a guidance mechanism. These observations further suggest that ephrins are pruning signals for the elimination of excess axons.

In addition to axonal pruning, selective death of ganglion cells also occurs during the time of target innervation. Cell death is not dependent on the presence of the tectal target, indicating that it may be due to limiting amounts of trophic signals. Consistent with this view, components of the signaling system of the neurotrophic factor GDNF are expressed in the retina and the tectum (Yu et al., 1998). GDNF-family factors support neuronal survival through the interaction with a signal transducing tyrosine kinase receptor Ret and a ligand-binding coreceptor (Lindsay and Yancopoulos, 1996; Robertson and Mason, 1997). One of the coreceptors, GFR α -2, is transcribed at high levels in the tectum, presumably en-

trapping GDNF-family factors as target-derived neurotrophic activity to support the survival of retinal ganglion cells, which express the signaling receptor Ret (Yu et al., 1998). In addition, a different factor of the neurotrophin family, brain-derived neurotrophic factor, may also play a role in supporting the survival of retina ganglion cells (Herzog and von Bartheld, 1998; Ma et al., 1998). Thus a combination of axonal elimination and selective survival of retinal ganglion cells may be important for the formation of retinotectal map (figure 14.2; see color plate 6).

It remains unclear what signals prevent nasal axons from terminating in the anterior tectum. It has been suggested that other molecules such as trophic factors may be specifically expressed in the posterior tectum and attract only the nasal axons (Boxberg, Deiss, and Schwarz, 1993). Thus the concerted actions of negative signals, such as those from Eph molecules, and potential trophic interactions may be critical for the establishment of topographic maps.

Conclusions and perspectives

The development of topographic neural maps apparently requires the actions of multiple guidance cues and employs multiple guidance mechanisms. Axons are guided to the proper targets by a combination of positive and negative signals working in diffusible or contact-mediated forms, along with elimination of mistargeted axons or neurons. These different mechanisms are used in both pathfinding and precise target selection. The guidance molecules belong to a variety of different families. CAMs are likely to be contact-mediated positive cues that function as permissible axonal growth substrates during pathfinding or serve to stabilize correct projections at the targets. Neurotrophic factors may contribute to the development of neural maps by selectively supporting survival and/or tropic attraction of proper axons. Members of the Eph subfamily ligands and receptors occupy a uniquely important position in determining the topographic specificity of axon terminals. Such specificity may be achieved by repelling or eliminating mistargeted axons from the ligand-expressing inhibitory domains. Research in the past half century has contributed greatly to our understanding of the mechanisms of axonal guidance. However, undoubtedly many guidance cues remain to be discovered, and a true challenge in the future will be to fit all the puzzle pieces together. In addition, little is known about how these signals regulate axonal behavior; the elucidation of the downstream signaling pathways will likely be a major research focus.

15 The Reorganization of Sensory and Motor Maps after Injury in Adult Mammals

JON H. KAAS

ABSTRACT Sensory and motor maps in the brains of adult mammals are highly plastic. The mutability of the topographic structures of these maps has been most convincingly demonstrated in the larger, two-dimensional maps of sensory surfaces in primary sensory cortex after long-standing deactivations of part of the receptor sheet. More limited modifications of cortical maps have been demonstrated after changes in experience and learning. In addition, convincing changes in subcortical maps have been demonstrated in the thalamus and brain stem, suggesting that all levels of sensory systems are modifiable, even in the mature brain. Changes in maps have been demonstrated in a range of mammalian species and in the somatosensory, visual, auditory, and motor systems. Some alterations are instantaneous, reflecting adjustments in dynamic systems. Others emerge over minutes to weeks as a result of synaptic modifications, the play of neuromodulating systems, and the regulation of the neurotransmitters. In instances of massive deafferentations, such as after the loss of a limb, major reactivations of cortical maps occur, but over longer times of months. These reactivations appear to depend, in part, on the growth of new connections. These massive reactivations lead to misperceptions referred to the missing sensory surface. Rearrangements of sensory and motor maps in the mature brain may be responsible for improvements in sensorimotor skills with practice, useful adjustment to sensory loss and change, and recoveries from central nervous system damage, as well as misperceptions and malfunctions. A fuller understanding of the mechanisms of adult plasticity might lead to improved clinical treatments and the potentiation of favorable outcomes.

One of the major surprises to emerge from research on sensory systems over the last 20 years is that the internal structures of maps of sensory surfaces in the brain are extremely mutable, even in adult mammals. The developing brain was already known to be highly plastic, since the course of development could be greatly altered by injury to part of the pathway or by sensory deprivation. In contrast, some of the same manipulations seemed to have little effect on the mature brain or even brains at later stages of development. In addition, reli-

able sensory perception would appear to depend on a system that is rather stable in organization. Therefore, the organization of much of the mature brain has been considered to be fixed by the end of development. Yet, some capacity for reorganization in sensory-perceptual systems would seem necessary to account for the learning of sensorimotor skills, adjustments to changes in sensory inputs, and the considerable recoveries that often occur after focal brain damage. We now know that the details of cortical representations are dynamically maintained, that changes in sensory inputs and the significance of sensory inputs can alter response properties of neurons and the structure of sensory maps over short to long time courses, and that after injuries major changes in sensory maps are possible. Some alterations are of such extent that they can only be explained by the growth of new connections. The evidence for such flexibility in brain organization leads to some obvious questions. For instance, how do such changes occur? Are they useful or harmful, and, either way, how can we control them? And, are all parts of the cortex, or brain, equally flexible, or do early and higher-order fields differ? While we have only partial answers to these and related questions, the usefulness of answering them is clear. But it is important to recognize that even after 20 or more years of intensive research, we are at the early stages of understanding the extent and nature of plasticity in the adult brain.

One of the current limits on our understanding is that only a few regions of the brain have been extensively studied. Many of the studies have been of the mutability of the hand map in primary somatosensory cortex of monkeys. A concentration of efforts on this cortex might seem strange, until one considers the technical advantages that this cortex offers. First, one needs a convincing way of demonstrating brain changes. The primary somatosensory representation is extremely precise and orderly, and the portion representing the hand in primates is rather large. The representation is two-dimensional, in

JON H. KAAS Department of Psychology, Vanderbilt University, Nashville, Tenn.

contrast to the more complex, three-dimensional, smaller subcortical representations, and the hand region of primary somatosensory cortex, at least in some primates, is exposed on the surface of the brain. These advantages allow alterations in cortex to be determined, even with relatively imprecise measuring methods, such as microelectrode mapping procedures.

As a result of concentrated efforts on a few favorable preparations, such as hand cortex in primates, we know a lot about the mutability of these structures. We also have enough evidence to say that many regions of cortex across many species of mammals are changeable, but we are uncertain if primary sensory cortex is more or less changeable than higher-order areas. However, there is evidence that cortical representations can be more mutable than subcortical representations.

The focus of this chapter is the effects of deactivating injuries to sensory systems, especially to the somatosensory system of primates. One reason for this focus is that the alterations in sensory inputs produced by damage have produced the largest changes in cortical organization, and thus the clearest evidence for plasticity in the mature brain has come from such deprivation experiments. Nevertheless, sensory experience and learning produce alterations in cortical circuits, and the accumulated evidence is now rather compelling (see chapter 16). However, we feel that the larger and more obvious changes produced by some types of injuries are especially interesting because they are not easily explained by simple adjustments in synaptic strengths. Thus the larger map reorganizations raise the issue of new neuronal growth in the mature brain. In addition, they raise the possibility of unwanted as well as desirable perceptual consequences.

Normally, sensory representations are relatively stable across time and across individuals

The hallmark of primary sensory cortex is the presence of an orderly and detailed representation of a sensory surface. It is the consistency of this representation across time and individuals that allows compelling evidence for mutability to be obtained. Thus the permanence of map organization allows changes that are due to a manipulation to be demonstrated by means of before-and-after measurements in the same animal, and it is the consistency of map organization across members of the same species that allows a group of normals to serve as controls for a group of manipulated individuals. While the variability of even primary sensory maps has been stressed on occasion (e.g., Merzenich et al., 1987), published maps of sensory cortex reflect measurement errors as well as biological variability. Cortical maps tend

to be highly consistent in instances where measurement error is greatly reduced. Extreme consistency, for example, is apparent in the morphological reflection of the somatotopy of S1 in rats and mice, where the arrangement of the so-called barrel field is remarkably stable across individuals, at least those born with a normal number of facial whiskers (Welker and Van der Loos, 1986). A similar consistency across individuals has been reported for the anatomical isomorph in S1 of the nose of the star-nosed mole (Catania and Kaas, 1997). While some might argue that S1 in primates is more variable, we recently discovered that the representations of the fingers and palm are visible in appropriately processed brain sections through area 3b of monkeys, and this easily and accurately measured histological map is extremely consistent across individuals (Jain, Catania, and Kaas, 1998). Furthermore, the morphological map is not altered by manipulations that greatly change the physiological map, and thus the morphological map can serve as a reference for changes induced by manipulations. Even with the possibility of considerable measurement error, studies across laboratories, experimental groups, and recording conditions have revealed little variability in the response properties of neurons, the receptive field sizes of neurons, and the basic somatotopy revealed by neuronal populations in area 3b of macaque monkeys (Pons et al., 1987).

The dynamic nature of sensory maps

Any alteration in the pattern of input from a sensory surface would, of course, be immediately reflected in changes in the central maps activated by those inputs. But the changes are more complex than simple removals or additions because of convergences and divergences in the connection patterns and subtle differences in these patterns for excitatory and inhibitory connections. Thus removing the inputs from a finger with local anesthetic, for example, might not silence cortex or subcortical structures normally devoted to that finger because weak inputs to that cortex related to adjoining fingers might be less inhibited (Rasmussen and Turnbull, 1983; Kelahan and Doetsch, 1984; Calford and Tweedale, 1991; Pettit and Schwark, 1993; Rasmussen, Louw, and Northgrave, 1993; Doetsch et al., 1996). These immediate consequences of rebalancing inhibitory and excitatory circuits (see Xing and Gerstein, 1996; Nicolelis, 1997, for review) have been described as the “unmasking” of silent synapses (P. D. Wall, 1977) or more recently as “disinhibition” (Calford and Tweedale, 1988). The evidence for such immediate changes tells us a great deal about the nature of the circuits in the system and how they normally operate. Sim-

ilar immediate changes in neuron receptive field properties, including receptive field sizes, can be induced by modifications in the activating stimuli. For example, the responses of visual neurons in visual cortex to line segments within the receptive field may be enhanced by similarly oriented line segments outside the receptive field, but inhibited by such segments of other orientations, suggesting a neural mechanism for the perceptual linking of line segments and the salience of segments of similar orientations. Many features of perception may depend on such dynamic features of cortical circuits (see Gilbert, 1998).

Other features of neurons and sensory maps may change rapidly with stimulus conditions. Many rapid changes may result from the modulation of local circuits by inputs from other structures (Castro-Alamancos and Connors, 1996). Brainstem neuromodulatory centers, such as the raphe nuclei and locus coeruleus, project widely to affect many neurons simultaneously as a result of changes in alertness, motivation, and emotional state (e.g., Juliano et al., 1990). In a similar but more focused manner, the activation of pain afferents by capsaicin injections in the skin appears to produce tonic activity in fibers that influence inhibitory interneurons and thus modulate receptive field sizes of neurons throughout the dorsal column–medial lemniscal system (Calford and Tweedale, 1991; Rasmusson, Louw, and Northgrave, 1993). Finally, synaptic strengths and thus neuronal properties and cortical maps can be rapidly modified by learning and experience (chapter 16; Weinberger, 1995; Ebner et al., 1997). Such stimulus-induced changes in synaptic strengths seem to depend on the entry of calcium into neurons through NMDA receptors following extended Hebbian rules (Bear, Cooper, and Ebner, 1987; Rauschecker, 1991; Benuskova, Diamond, and Ebner, 1994). During experience-related changes in mature brains, the synaptic modifications may be permitted or potentiated by the neuromodulatory actions of acetylcholine release via projections from nucleus basalis (Dykes, 1990, 1997; Juliano, Ma, and Eslin, 1991; Wienberger, 1995; Kilgard and Merzenich, 1998).

Slowly emerging reorganizations of cortical maps

Many alterations in sensory maps occur over longer time periods of hours, weeks, and even months. These more slowly emerging changes are especially interesting because they potentially involve mechanisms in addition to adjustments in the dynamic balance of the neuronal network and rapid synaptic modifications, especially activity-dependent effects on the expression of genes that can lead to neurotransmitter regulation (E. G. Jones, 1993) and the release of trophic factors (Levine and Black,

1997) that alter the growth of dendrites and axons. The products of early gene expression, as a result of increases or decreases in neural activity, can be measured in minutes to hours (e.g., Melzer and Steiner, 1997).

One of the now classic demonstrations of cortical plasticity involved the reorganization of the hand representation in S1 (3b) of monkeys after section of the median nerve to the skin of the thumb half of the glabrous hand (Merzenich et al., 1983a). This procedure deprives about half of the hand representation of its normal source of activation. Although some neurons in this deprived territory acquire new receptive fields on innervated parts of the hand immediately or very rapidly (Silva et al., 1996), probably due to disinhibition, the extent of the reactivation gradually increases over a period of weeks until all deprived neurons are highly responsive to tactile inputs on the hand (figure 15.1; Merzenich et al., 1983b). The recovery is largely from inputs from the hairy back of the hand, and the cortical reactivation is highly somatotopic, with regions formerly devoted to the glabrous surfaces of digits 1–3 activated instead from inputs from the dorsal skin of digits 1–3 in the same sequence.

The original interpretation of this recovery was that it was based on the potentiation of weak and ineffective synapses in the fringes of highly overlapping thalamocortical axon arbors, but subsequent studies have revealed that this interpretation is too simple. First, an investigation of the nature of the map of the hand in the first relay of tactile information in the cuneate nucleus of the dorsal column–trigeminal complex suggested an involvement at this initial level. Anatomical studies showed that afferents from each digit terminate in a separate cluster of neurons in the cuneate nucleus, but inputs from the dorsal and glabrous surfaces of the same digit terminate in the same cluster of cells (Florence, Wall, and Kaas, 1991). Thus it would require only a limited rewiring or potentiation of local connections in the cuneate nucleus for neurons responsive to glabrous skin to become responsive to dorsal skin. Second, reactivation of hand cortex can be incomplete if the radial nerve to the dorsal hand is sectioned in addition to the ulnar or median nerve to the glabrous hand (Garraghty et al., 1994), but reactivation is complete if both the ulnar and median nerves are sectioned (Garraghty and Kaas, 1991a). Thus the inputs from the dorsal hand are especially potent in reactivating cortex. Third, recordings obtained in the thalamic target of the cuneate nucleus, the hand subnucleus of the ventroposterior nucleus, revealed that considerable reactivation of deprived neurons occurs at this level of the system after median nerve section (Garraghty and Kaas, 1991b). More directly, reactivation of some of the deprived

F. Reorganization after D3 removed

neurons occurs in the cuneate nucleus (Xu and Wall, 1997), as postulated. Yet, the outcome in cortex is not as simple as switching neurons in the cuneate nucleus from a glabrous to a hairy skin source of activation, together with the relay of this switch in activation to the thalamus and cortex. Instead, it seems likely that an incomplete and relatively weak reactivation of neurons in the cuneate nucleus is relayed and potentiated in the thalamus and potentiated again when relayed to the cortex. Much of this potentiation may depend on NMDA receptors, since chronically blocking these receptors prevented the reactivation and reorganization of somatosensory cortex (Garraghty and Muja, 1996). The reactivation of cortex may also be facilitated by the down-regulation of GABA expression in the deprived cortex as a consequence of a period of reduced neuronal activity (Garraghty, Lachica, and Kaas, 1991).

FIGURE 15.1 Primary somatosensory cortex (area 3b) reorganizes after median nerve section or finger loss in monkeys. (A) The locations of area 3b and the portion devoted to the hand on a lateral view of the brain of an owl monkey. This New World monkey has only a shallow dimple in cortex medial to the hand representation, rather than a central fissure, as in humans. Thus area 3b is largely in the exposed surface of the brain. (B) The glabrous hand is represented in area 3b as if the palm were split from the ventral wrist toward digit 3, and spread out on cortex with digits 1–5 in a lateromedial sequence and the palm caudal to the digits. The dorsal surface is poorly represented (stippled) in a variable manner. Often, the dorsal skin of the digits and hand are represented in narrow bands of tissue medial and lateral to that of the glabrous hand (see Jain, Florence, and Kaas, 1998, for review). (C) The hand representation is distorted into a roughly rectangular shape in area 3b, with a compression of the length compared to the width of the hand. (D) The median nerve subserves about half of the glabrous hand from the thumb (D1) to part of the middle finger (D3). Thus section of the median nerve deprives most of the lateral half of the hand representation of its normal source of activation (hatched region). (E) The deprived region of the hand representation, the former territory of the median nerve, becomes reactivated over about one month of recovery by inputs largely from the hairy, dorsal surface of the hand via the intact radial nerve. Some expansion of the representations of glabrous D3 and P3 occurs (arrows). The reactivation is somatotopic, with the former territories of glabrous D1–D3 and adjoining pads acquiring responsiveness to stimulation of dorsal skin of D1–D3 and adjoining pads (see Merzenich et al., 1983a, 1983b). (F) In another type of deprivation, the loss or removal of a finger, the deprived territory of the missing finger becomes responsive to inputs from the adjoining fingers and palm (see Merzenich et al., 1984; Jain, Catania, and Kaas, 1998). Digits and pads of the hand are traditionally numbered, and insular (I), hypothenar (H), and thenar (T) pads are indicated.

Whatever the mechanisms, the consequences of nerve damage can be completely reversible. If the median nerve is crushed, rather than sectioned, so that it can regenerate accurately to original skin targets, the regenerated nerve reclaims its lost cortical territory, and neurons in this territory recover receptive fields that are almost identical in skin locations to those they had originally (J. T. Wall, Felleman, and Kaas, 1983).

The series of experiments on the effects of median nerve damage in monkeys leads to several conclusions. First, subcortical structures are clearly subject to reorganization and reactivation. There is a history of earlier evidence for spinal cord and brainstem plasticity in adult mammals, but difficulties of measuring limited changes in the small subcortical maps led to uncertainties about at least some of the claims (see Snow and Wilson, 1991). The reactivation of the large hand subnucleus of the ventroposterior nucleus by preserved inputs from the back of the hand after median and ulnar nerve section provides strong evidence for subcortical plasticity

(Garraghty and Kaas, 1991b), especially in conjunction with comparable results from a number of more recent studies (e.g., Pettit and Schwark, 1993; Rasmusson, 1996; Xu and Wall, 1997; Parker, Wood, and Dostrovsky, 1998). Second, normal map structure may differ from level to level in a processing system, so that relatively minor somatotopic adjustments at one level, such as the substitution of dorsal skin for glabrous skin inputs in the cuneate nucleus, can appear larger at subsequent levels (see Kaas and Florence, 1997). Third, modifications at early stages of processing in a hierarchical system can be amplified by modifications at subsequent stages. Even at early stages of cortical processing, the observed results involve a combination of cortical and subcortical mechanisms. Furthermore, due to feedback connections, cortical changes impact on subcortical representations (Ergenzinger et al., 1998). Nevertheless, we do not suggest that subcortical changes always play a major or even a notable role. We know, for example, that the second somatosensory area of monkeys, S2, depends on inputs from areas of anterior parietal cortex (Pons et al., 1987; Garraghty, Pons, and Kaas, 1990) and that lesions of the hand representations in these areas deactivate the hand portion of S2, which subsequently becomes responsive to other remaining inputs from anterior parietal cortex (Pons, Garraghty, and Mishkin, 1988; figure 15.2). It seems unlikely that the reorganization of S2 depends on subcortical rather than cortical mechanisms. We also know that restricted lesions of the retina in cats or monkeys deactivate the retinotopic portion of the thalamic relay, the lateral geniculate nucleus, and primary visual cortex, but the amount of reactivation by parts of the retina surrounding the lesion is very limited in the lateral geniculate nucleus (e.g., Darian-Smith and Gilbert, 1995; Baekelandt et al., 1994) compared to the extensive reactivation of cortex (figure 15.3; see Chino, 1997).

The subcortical and cortical changes in map organization demonstrated after peripheral nerve section in monkeys constitute only a fragment of an impressive collection of evidence that deactivations of populations of central nervous system neurons by receptor damage are followed by reactivations by remaining inputs. Positive results have been obtained from a range of manipulations across a number of mammalian species. In monkeys with amputated or missing digits, the primary somatosensory cortex normally responsive to those digits typically became responsive to inputs from adjoining digits (figure 15.1F), although some unresponsive cortex may remain (Merzenich et al., 1984; Calford and Tweedale, 1991; Code, Eslin, and Juliano, 1992; Manger, Woods, and Jones, 1996; Jain, Catania, and Kaas, 1998). Similarly, the cortical territories of

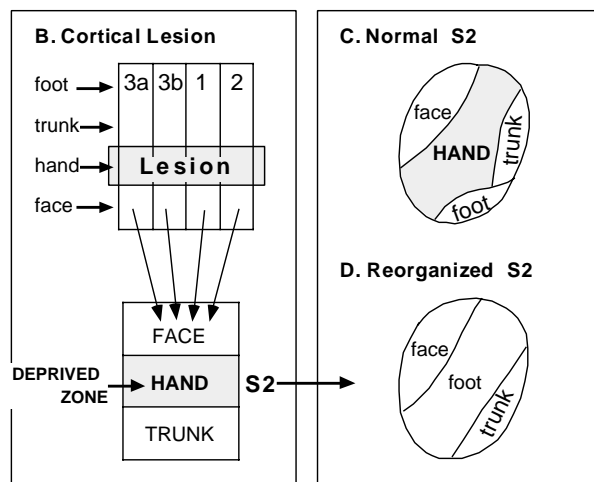

FIGURE 15.2 Reorganization of the second somatosensory area, S2, after lesions of the hand representations in anterior parietal cortex. Each of the four fields of anterior parietal cortex represents the body from foot to face in a mediolateral sequence (see Kaas, 1983). The activation of S2 depends on direct projections from these four fields, especially area 3b (Pons et al., 1987; Garraghty, Pons, and Kaas, 1990). Thus a lesion of the hand regions of these four fields deactivates the hand portion of S2. This cortex recovers responsiveness, largely to the foot (Pons, Garraghty, and Mishkin, 1988). (A) The locations of somatosensory areas on a lateral view of the brain of a macaque monkey. S2 can be seen on the upper bank of the opened lateral sulcus. Areas 3a and 3b are in the opened central sulcus, while areas 1 and 2 are largely on the brain surface. (B) A schematic of the four areas and S2, with the depriving effects of a lesion of hand cortex. (C) The normal somatotopy of S2 including a large representation of the hand. (D) The reorganized S2 with hand cortex reactivated by inputs from the foot.

missing digits of the large hand representations in S1 of raccoons became responsive to inputs from remaining digits (figure 15.4). Comparable results have been reported after digit loss in bats (Calford and Tweedale, 1988) and cats (Kalaska and Pomeranz, 1979) and after

FIGURE 15.3 The reorganization of primary visual cortex following lesions of the retina. The deactivated cortex becomes responsive to parts of the retina adjoining the lesion. Because visual cortex is activated by both eyes, either lesions are retinotopically matched in both eyes, or all inputs are removed from the eye without a lesion (*) in order to completely deactivate a region of cortex.

(Lower left) A dorsal view of a cat brain showing a left eye with a 5° retinal lesion and the course of retinal projections (arrows) to the thalamus of both hemispheres. Recordings were made in primary visual cortex (V1—dashed line) of the right hemisphere.

(Lower right) A dorsal view of caudal visual cortex of the left hemisphere with some of V1 of the medial wall folded out, so that two rows of recording sites (numbered dots) are visible.

(Above) A portion of the left visual hemifield, marked in degrees along the zero horizontal meridian (HM), and showing the zero vertical meridian (VM). The projected location of the lesion of the retina of the left eye is outlined, together with receptive fields for neurons in the two rows of recording sites. Receptive fields for row A (see lower right) form a normal and orderly progression from temporal vision to the VM for a mediolateral sequence of recording sites toward the lateral border of V1. Receptive fields for row B, which passes through deprived cortex, are abnormally arranged so that receptive fields pile up on each side of the scotoma caused by the retinal lesion. Neurons at sites 2–4 acquired new receptive fields from retina outside of the lesion. Neurons at site 3 had two receptive fields, one on each side of the lesion. (Based on Kaas et al., 1990.)

A. S1 Hand in Raccoon

B. Normal Representation of Digits

C. After Removal of D3

FIGURE 15.4 Reorganization of somatosensory cortex after digit removal has also been convincingly demonstrated in raccoons, which have a large, highly orderly representation of the glabrous hand in primary somatosensory cortex, S1. (A) The location of S1 and the hand representation of pads and digits 1–5 on a dorsolateral view of the brain. (B) Normal representation of the digits in S1. (C) After removal of D3, the deprived cortex becomes activated by inputs from D2 and D4, and the palm adjoining D3. (Based on Kelahan and Doetsch, 1984; Rasmusson, 1982).

nerve damage in rats (J. T. Wall and Cusick, 1984). Cortical reorganization has been demonstrated even in humans, but the limited resolution of the noninvasive brain-imaging techniques (fMRI) has meant that only the larger reorganizations following limb amputations are obvious (see next section). While studies of cortex have concentrated on the detailed somatotopic map in S1 (3b), reorganizations have also been demonstrated in areas 3a and 1 of anterior parietal cortex (Merzenich et al., 1983a; Jain, Catania, and Kaas, 1997a) and in S2 (figure 15.2; Pons, Garraghty, and Mishkin, 1988) of monkeys.

As already noted, there have been many demonstrations of the filling in of cortical zones of deactivation after focal lesions of the retina in cats and monkeys (figure 15.3; Chino, 1997), and there is some evidence for the reorganization of the middle tempo-

FIGURE 15.5 The reorganization of deactivated auditory cortex. (A) A dorsal view of the left hemisphere of a macaque monkey brain with cortex over the lower bank of the lateral sulcus (S) cut away to reveal the location of primary auditory cortex (A1). (B) Primary auditory cortex (oval) normally is tonotopically organized in a roughly rostrocaudal fashion with low tones (L) activating rostral locations, middle frequency tones (M) activating middle locations, and high tones (H) activating caudal locations. (C) Months after a high-frequency cochlear hearing loss produced by ototoxic drugs, neurons in caudal A1 no longer responded to high tones. Instead, these neurons responded to middle-frequency tones, and the representation of middle tones expanded (arrows). (Based on Schwaber, Garraghty, and Kaas, 1993).

ral visual area, MT, of monkeys after partial lesions of MT (Newsome and Pare, 1988; Yamasaki and Wurtz, 1991) or lesions of its activating input from V1 (Kaas and Krubitzer, 1992). An advantage of the visual system for studies of reactivation is that the reactivated neurons can be easily studied quantitatively for changes in response properties. Consistent with the qualitative observations from somatosensory cortex, visual neurons that acquire new receptive fields as a result of retinal lesions are little changed in response properties (Chino et al., 1995; Chino, 1997). Primary auditory cortex has also been shown to reorganize (see Kaas, 1996) after partial hearing loss in adult rodents (Robertson and Irvine, 1989), cats (Rajan et al., 1993), and monkeys (figure 15.5; Schwaber, Garraghty, and Kaas, 1993).

Evidence for plasticity in primary motor cortex comes from microstimulation experiments where a systematic map of movements can be demonstrated by evoking movements from many locations in cortex with low levels of electrical stimulation delivered with microelectrodes. After the loss of the muscle targets of part of motor cortex (Donoghue, Suner, and Sanes, 1990; Sanes, Suner, and Donoghue, 1990) by section of the motor nerve to the movable whiskers of the face in rats,

A. Rat Cortex

FIGURE 15.6 The reorganization of primary motor cortex, M1, after section of the motor nerve to the movable vibrissa of the face. (A) A dorsolateral view of a rat brain showing the locations of primary motor cortex, M1, and somatosensory cortex, S1. (B) The normal somatotopy of the motor map in M1 (left) is modified over weeks of recovery after nerve section so that electrical stimulation of vibrissa cortex comes to evoke movements of the forelimb, eyelid, and eye. (Based on Sanes, Suner, and Donoghue, 1990).

low levels of electrical stimulation of the vibrissa cortex come to evoke movements of the forelimb and eye (figure 15.6). Similar reorganizations of human motor cortex have been demonstrated with transcranial magnetic stimulation (see Chen et al., 1998), and in monkeys with microstimulation (Schieber and Deuel, 1997). Additionally, lesions of parts of M1 for specific movements are followed by recoveries where stimulation of remaining parts of M1 can evoke the movements of the missing cortex (Nudo and Milliken, 1996; Nudo et al., 1996; Nudo, Plantz, and Milliken, 1997). Thus we conclude from these rather dramatic experiments that the mature brain, perhaps especially cortex, is not fixed in functional organization, and cortical areas of several levels in all major systems and across mammalian species can change.

Most of the changes in sensory and motor representations described are of a size that is limited enough to be compatible with explanations based largely or solely on alterations in the synaptic strengths of existing connections. Recently, however, there have been a number of demonstrations of cortical reorganizations of a very large scale following the loss of most or all of the afferent inputs from a limb or even larger portions of the body. The first evidence that such massive changes occur come from studies of somatosensory cortex in monkeys 12 years or more after complete deafferentation of the arm by section of the relevant dorsal roots as they enter the spinal cord. Originally, these monkeys were studied behaviorally. Fortunately some were available for a microelectrode mapping study of somatosensory cortex. The surprising and remarkable finding from these recordings was that the large mediolateral extents (10 mm or more) of areas 3b and 1 that formerly represented the hand, wrist, and arm in these monkeys, were completely responsive to inputs from the chin and jaw (Pons et al., 1991). Thus neurons over a large expanse of cortex responded vigorously to the displacement of hairs and light touch on a limited portion of the face. The reactivated cortex was just medial to cortex that normally responds to the face, and this cortex continued to respond to the face. These results raised two important questions. First, what are the perceptual consequences of such an extensive reorganization of the somatosensory system? Second, how is such an extensive reorganization mediated?

The evidence for massive cortical reorganization immediately attracted the attention of investigators interested in the sensation of the existence of a missing limb, the phantom limb, that is typically reported by adult humans with amputations. The existence of such sensations has long been recognized, and they have been attributed to spontaneous or other neural activity in the portions of the somatosensory system formerly related to the missing limb (e.g., Melzack, 1990). Soon after the report on cortical reorganization in monkeys, Ramachandran, Rogers-Ramachandran, and Stewart (1992) drew attention to highly significant behavioral observations on phantom limbs. In brief, they noted that a light touch on the face of a patient with a missing arm led to the sensation of touch, not only on the face, but also on the phantom of the missing arm. Furthermore, touches on different parts of the face resulted in sensations on different parts of the phantom. To explain these observations, Ramachandran, Rogers-Ramachandran, and Stewart (1992) assumed that amputations are followed by massive cortical reorganization, as in deafferented

monkeys. They further postulated that touching the face activates the reorganized cortex, and activation of the reorganized cortex signals touch on the missing limb, rather than the real source of activation, the face. Further study revealed that sensations on the missing limb can also be triggered by touches on the skin of the stump of the missing limb (Ramachandran, 1993; Halligan et al., 1993; Yang et al., 1994; Aglioti, Bonazzi, and Cortese, 1994). However, the hypothesis that the triggered phantom sensations are caused by the activation of reorganized parts of primary somatosensory cortex does not easily account for all observations on phantom limbs. Most notably, trigger zones on the arm can emerge for sensations referred to a missing hand within a day of the loss of the hand (Doetsch, 1997). As yet, there is no evidence for such rapid reactivation of primary somatosensory cortex (see below).

At the time when Ramachandran, Rogers-Ramachandran, and Stewart (1992) proposed that the face activated hand cortex in humans with forelimb amputation, such extensive reorganization of cortex was only known for monkeys with a complete deafferentation of the forelimb (Pons et al., 1991), and it was not certain what would happen after a more limited sensory loss. However, monkeys, like humans, sometimes receive injuries that require a therapeutic amputation of a limb, and it soon became possible to study cortical organization in three such monkeys. Microelectrode recordings from these monkeys with forelimb or hand amputations revealed that hand cortex was completely reactivated by inputs from the stump of the limb, and to some extent the face (Florence and Kaas, 1995). The results indicated that massive reorganization of somatosensory cortex can follow the loss of inputs from the hand or forelimb in primates (also see Florence, Taub, and Lyon, 1997), and thus cortical reorganization could account for the face and stump trigger zones for sensations on the phantom in humans. Unfortunately, the results did not provide any information on the length of time it takes for reorganization, since the monkeys were studied 1–13 years after their amputations. However, the results did provide an important clue about the possible sources of the reactivation. In each monkey, an anatomical tracer was injected into the skin of the stump of the amputated limb. The transportation of this tracer through sensory nerves of the stump to the spinal cord and cuneate subnucleus of the brain stem revealed axon terminations in normal locations for the representation of the arm, but also a sparse distribution of axons in the part of the nucleus where the hand is normally represented. These anatomical results generated the hypothesis that axons from the arm had sprouted to grow into the deafferented part of the cu-

neate nucleus formerly devoted to the hand. While this sparse reinnervation presumably would activate only some of the deprived neurons on the cuneate nucleus, the divergence and convergence of projections from the cuneate nucleus to the ventroposterior nucleus of the thalamus would result in a larger population of reactivated neurons, and the divergence of thalamocortical projections, together with the framework of lateral, intrinsic connections in somatosensory cortex, would lead to more effective reactivations at these higher levels.

The use of noninvasive imaging methods has allowed the issue of brain reorganization after amputations to be directly examined in humans. Such imaging studies provided further evidence that face and stump inputs come to activate hand cortex in humans with forelimb amputations (Yang et al., 1994; Elbert et al., 1994; Flor et al., 1995; Knecht et al., 1996). Remarkable additional evidence came from a study of the results of recording from neurons in the ventroposterior nucleus of humans with amputations, and electrically stimulating the same neurons (Davis et al., 1998). In normal, undeprived portions of the somatosensory thalamus, these investigators found that the sensations produced by microstimulation were referred to the same locations as the receptive fields of the neurons at the sites of electrical stimulation. But in some amputees, stimulating neurons with receptive fields on the stump of the missing limb produced sensations referred to the missing limb. The results indicate that reorganization of deprived parts of the somatosensory system, as observed in cortex, had already occurred at the level of the thalamus, and that the reactivated neurons continued to retain their original meaning of stimuli on the missing limb. This finding, of course, does not suggest that sensations on the missing limb are mediated in the thalamus, since these neurons are part of a complex system that includes many levels of somatosensory cortex that would also be activated by the electrical stimulation of thalamic neurons. Nevertheless, the evidence is now rather compelling that amputations can produce extensive reorganizations of the somatosensory system. Such reorganizations may be expressed subcortically at the level of the thalamus, and reactivated neurons retain the original significance and signal misperceptions of touch on the phantom limb.

Are such massive reactivations mediated, at least to some critical extent, by the growth of new connections? Further evidence for new growth came from studies of the time it takes for massive cortical reorganization, since new growth would take some time to occur. The time course of reactivation was possible to study in monkeys with unilateral section of forelimb afferents in

the dorsal columns of the spinal cord (Jain, Catania, and Kaas, 1997b, 1998a). There is a history of many years of behavioral and electrophysiological studies of the effects of dorsal column section in monkeys, and a surprising finding is that the behavioral consequences are rather mild (e.g., Makous, Friedman, and Vierch, 1996). Thus, soon after unilateral sections, monkeys climb about and retrieve food with the affected limb, although not as skillfully as with the normal limb. Despite these rather limited behavioral changes, the hand region of area 3b of somatosensory cortex of monkeys was completely deactivated by dorsal column section above the level where afferents enter from the hand, while the more lateral cortex devoted to the face responded normally to touch on the face (figure 15.7B). However, if the lesion was incomplete so that a fraction of the afferents from the hand remained, these afferents continued to activate cortical neurons, and the complete hand territory of cortex gradually became reactivated by these preserved inputs from the hand (figure 15.7D, E). If the dorsal column section was complete, no reactivation of this cortex by hand afferents occurred even after months. Instead, the hand cortex became reactivated by preserved inputs from the face and a few preserved afferents from the anterior arm that enter the spinal cord above the level where afferents enter from the hand (figure 15.7C). Indeed, many neurons in hand cortex became responsive to tactile stimuli on either the face or anterior arm. Most importantly, the reactivation of somatosensory cortex by face inputs occurred slowly, emerging only after six to eight months of recovery. This slow development suggests that a critical feature in the reactivation is the sprouting and growth of new connections, possibly the sprouting and growth of axon collaterals of afferents from the face (and stump for amputations) into the portions of the cuneate nucleus of the brain stem normally activated by the hand as proposed by Florence and Kaas (1995).

The proposal that reactivation is based on the formation of new connections is somewhat unconventional, since new growth in the mature central nervous system is expected to be very limited (see Florence and Kaas, in press, for review). Yet, there is evidence that the terminations of crushed nerves sprout in the spinal cord of monkeys (Florence et al., 1993; see Kapfhaminer, 1997, for review of axon sprouting in the spinal cord) and that afferents grow into new brainstem territories after limb amputations (Florence and Kaas, 1995) or dorsal column section (N. Jain, unpublished observations). Since the new growth in the brain stem is sparse, the effects of these reinnervations are most likely enhanced at higher levels in the system so that many neurons are

FIGURE 15.7 The reorganization of somatosensory cortex after dorsal column lesions. The dorsal column constitutes the major spinal cord pathway for ascending afferents from cutaneous and muscle receptors. Section of the dorsal column at high cervical levels removes this input from the hand and most of the arm, as well as lower parts of the body, while leaving inputs from the face intact. (A) The normal organization of the lateral portion of area 3b in owl monkeys (see figure 15.1 for locations on brain). The upper and lower face are represented in two ovals of cortex laterally, the digits in a lateromedial sequence from 1–5 more medially and rostrally, the pads of the palm, caudally, and the wrist and arm medially. (B) After a complete dorsal column lesion of one side, the opposite hand region and more medial cortex becomes completely unresponsive to touch and hair movement. Some medial cortex may remain responsive to preserved inputs from the anterior arm, and lateral cortex remains normally responsive to touch and hair movement on the face. This complete deactivation persists for months. (C) After 6–8 months of recovery from contralateral dorsal column section, hand cortex becomes responsive to touch and hair movement on the face. Some of the more medial cortex may respond to both the face and the anterior arm. (D) Incomplete dorsal column lesions leave some of the hand representation responsive to tactile stimulation of the hand. Within the first few days of recovery, this activation is somatotopically appropriate, and much of the hand representation is unresponsive (Silent). (E) Within weeks of an incomplete dorsal column lesion leaving some inputs from the hand intact, these preserved inputs come to activate much or all of hand cortex. (F) After months of recovery after an incomplete dorsal column lesion, many locations in hand cortex respond to both hand and face inputs. This result seems to reflect both the more rapid potentiation of preserved inputs from the hand and the slower potentiation of preserved inputs from the face. (Modified from Jain, Florence, and Kaas, 1998.)

reactivated in the thalamus (Davis et al., 1998), and the cortical reactivation is even more effective. Reactivations in cortex may even depend in part on the growth of new connections in cortex. Darian-Smith and Gilbert (1994) provided anatomical evidence that the horizon-

tal connections in visual cortex sprout to become more dense in regions where neurons have become reactivated after being deprived by long-standing retinal lesions. Similarly, injections of anatomical tracers in somatosensory cortex of monkeys with limb amputations provided evidence for the growth of new and more extensive horizontal connections within the deprived but recovered cortex (Florence, Taub, and Lyon, 1997). New growth may occur at other levels of the somatosensory and visual systems as well (e.g., Baeke-landt et al., 1994), and new growth may include the extension of dendrites of cortical and subcortical neurons (e.g., T. A. Jones and Schallert, 1994).

The anatomical results after massive deafferentations demonstrate the possibility of considerable new growth in the mature central nervous system (also, see Aguayo, 1985). Glial cells of the central nervous system appear to generate molecules that normally inhibit axon growth, and thus new growth can be promoted by interfering with these molecules (e.g., Z'Graggen et al., 1998; see Schwab, 1996, for review). It is not certain why new growth of an extensive nature takes so long to emerge, but it may take time for inducing factors (e.g., Cohen-Cory and Fraser, 1995) to be expressed, as well as time for new growth (see Florence and Kaas, in press). While new growth may be important in many reactivations, new growth may provide only a framework for recovery, and many other factors important in less massive reactivations undoubtedly also contribute.

Conclusions

As a result of a large number of studies of cortical and subcortical plasticity of sensory and motor systems in adult mammals, especially during the last few years, a number of conclusions are now supportable.

1. The detailed structure of normal representations is dynamically maintained. Alterations in inputs, activations of modulating systems with emotional state and attention, and even changes in stimulus conditions can produce immediate changes in the dynamic balance within systems so that receptive field properties, receptive field sizes and locations, and map topography change. Such rapid changes are typically quite reversible, but they may lead to changes in synaptic strengths and thus to more persistent alterations.

2. Alterations produced by prolonged, localized sensory or electrical stimulation or by sensory deprivations may lead to activity-induced modifications in neurotransmitter and neuromodulator expression, the local growth of axons and dendrites, and alterations in synaptic strengths. Synaptic weights also may be altered by

experience and learning according to modified Hebbian rules.

3. Reorganizations of sensory and motor maps occur in all major systems and at subcortical as well as cortical levels. Modifications accumulate and amplify across serial levels of processing. Cortical areas, due to a system of horizontal connections, may be more modifiable than subcortical stations.

4. Some types of recovery are best understood in terms of the internal structures of subcortical maps. The substitution of dorsal skin inputs for glabrous skin inputs, for example, appears to involve rather local and limited synaptic changes in the cuneate nucleus of the brain stem that results in an impressively large reorganization of the cortical map.

5. Some types of reorganization, such as those that occur after major sensory deafferentations, take months to emerge. These major reactivations appear to depend on the extensive sprouting and growth of axons to form new connections. The massive reorganizations lead to misperceptions, and often unwanted sensations. Nevertheless, the potential for new growth holds promise for many clinical applications, and new growth may be important in other recoveries, such as those that occur after stroke.

16 Cerebral Cortical Plasticity: Perception and Skill Acquisition

GREGG H. RECANZONE

ABSTRACT Cerebral cortical plasticity has been demonstrated in a variety of different mammals, following a number of different peripheral and central nervous system manipulations. The reorganization of cortical representations has been implicated in the ability to acquire perceptual and motor skills throughout normal life. This chapter presents evidence from a variety of studies which indicates that cortical plasticity occurs in normal, intact animals and humans, and that these changes in representations are correlated with changes in both motor skills and sensory perceptions.

One of the central goals in neuroscience, particularly in cognitive neuroscience, is to determine the neuronal mechanisms that generate perceptions. Very little is known about how action potentials transmitted throughout the nervous system allow individuals to perceive the complex world around them, to compare this representation of the world to past experience, and to initiate behaviors to achieve goals (e.g., eating, drinking, rest, lively conversation). Although both animal and human studies indicate that the cerebral cortex is integral in processing complex stimuli, very little is known of this structure beyond the presumed relevance of particular areas for specific functions. Although much knowledge has been gained over the past decades on how the individual neurons in a limited number of cortical areas respond to different stimuli, it is still unclear how these responses participate in perception.

While it may be agreed by many that the cerebral cortex is necessary for some perceptions, there is less consensus on how the cerebral cortex is actually functioning to create these perceptions. Further, one of the basic tenets of psychological studies since the late 1800s has been that individuals will improve at virtually any task with continued practice. It was presumed by James (1890) that this improvement in performance was made possible by a change, or “plasticity,” of the “organic materials” of the central nervous system.

The first real insights into how such changes could be manifest in the cerebral cortex came from studies examining the effects of peripheral nerve injuries on cortical “maps,” or representations of the sensory surface, in adult mammals (see Kaas, 1991, and chapter 15). The term *plasticity* is used to describe this capacity to change cortical representations in adults. In such studies denervation, or extensive behavioral use of a restricted sensory surface, results in a change in the central representation of that sensory surface. These results are consistent with the earliest reports of cerebral cortical function performed at the turn of the 20th century by Sir Charles Sherrington and colleagues. Their studies of the motor cortex of monkeys and great apes indicated that movement representations in the motor cortex could be altered over the course of several minutes, and that this effect was reversible (Graham Brown and Sherrington, 1912).

Several other studies have shown that cortical representations most likely reflect the stimulus history of the sensory surface being represented. For example, the cortical representation of the ventral body surface is larger in nursing rat mothers than in non-nursing female rats (Xerri, Stern, and Merzenich, 1994). The selective stimulation of two whiskers either experimentally (DeLacour, Houcine, and Talbi, 1987) or by trimming all but two adjacent whiskers (Armstrong-James, Diamond, and Ebner, 1994) results in many more neurons within the somatosensory cortex responding to both of the two whiskers. In primates, surgical fusion of two digits results in a zone of cortex in area 3b in which neurons have receptive fields that cross the suture line and respond to parts of both fused digits, in contrast to the normal situation where 3b neurons rarely, if ever, respond to stimulation of two digits (Allard et al., 1991; see also Merzenich et al., 1987). Finally, Jenkins and colleagues (1990) showed that training monkeys to attend to stimulation on the tip of one or two fingers results in an increased representation of the stimulated fingertips compared to the unstimulated fingers. Similar kinds of short- and long-term plasticity have been observed in the visual cortex as well as in human sub-

GREGG H. RECANZONE Center for Neuroscience and Section of Neurobiology, Physiology, and Behavior, University of California at Davis, Calif.

jects performing visual psychophysical tasks (see Gilbert et al., 1996; Gilbert, 1998).

These experiments provide evidence that cortical plasticity is not necessarily a response to the peripheral injury, but can also occur by changing the stimulation pattern across the skin. This finding further suggests that practice at a particular behavioral task, which generally results in an improvement in performance, would similarly be reflected by a change in the cortical representations of the relevant sensory or motor components of the task. For example, it could be reasoned that the increased representation of the ventral surface of the rats (Xerri, Stern, and Merzenich, 1994) or the fingertips of the monkeys (Jenkins et al., 1990) results in better perceptual acuity over that skin surface for that animal. The rest of this chapter will draw on selected examples from a variety of different experimental methodologies to address the central question: Are changes in cortical representations a reflection of normal cortical processes that underlie the ability to acquire new skills and behaviors?

Cortical plasticity and changes in perception invoked by classical conditioning paradigms

Early studies on the effects of classical conditioning on the response properties of neurons in the central auditory system have shown that there is a clear change in the functional tuning properties of neurons throughout the central auditory system. Some of the earliest examples are derived from studies in which awake adult rats were implanted with a series of electrodes that recorded the activity of spatially restricted neurons throughout the brain stem, thalamus, and cortex (Olds et al., 1972; Disterhoft and Stuart, 1976). In these experiments, neuronal activity was recorded during a period in which one of two different tones was presented or a food pellet was dispensed over the course of the first day. There was no temporal relationship between the tone and the food delivery, and thus no association between the two would be expected to be formed (pseudoconditioning). On the second day, however, one of the two tones always preceded the pellet delivery, while the other tone never preceded a food reward (conditioning). In these studies, after the conditioning period, the amount of activity of cortical neurons increased in response to the tone paired with the food delivery. This increase could be extinguished by returning to the pseudoconditioning procedure, now called extinction, where the tones and food delivery were no longer correlated (Disterhoft and Stuart, 1976). Similar kinds of effects were also observed in the noncortical regions as well, particularly the posterior thalamus and pretectal regions. Much smaller differences were noted in the main ascending auditory subcortical regions, the infe-

rior colliculus and the medial geniculate body of the thalamus (Disterhoft and Stuart, 1976).

A similar series of studies using a mild electrical shock to the forepaw as the unconditioned stimulus and the pupillary dilation reflex as the unconditioned response have extended these findings in the cat. The change in the response properties of neurons is more rapid in the auditory cortex than in the cochlear nucleus (Oleson, Ashe, and Weinberger, 1975). These changes are not, however ubiquitous throughout the central nervous system. Comparison of the conditioning effects of multiple-unit activity within the medial, ventral, and dorsal subdivisions of the auditory thalamus, the medial geniculate body (MGB), showed that neuronal responses changed only in the medial subdivision, and not in the ventral or dorsal regions of the MGB (Ryugo and Weinberger, 1978). This result is interesting in that the ventral division of the MGB has the anatomical connections and response properties consistent with those of a thalamic relay or lemniscal nucleus, whereas the medial division is more consistent with a lemniscal adjunct or nonspecific function.

More recent studies have expanded these observations by defining the response properties of single neurons to both conditioned and a series of nonconditioned stimuli (Diamond and Weinberger, 1986; Bakin and Weinberger, 1990; see Weinberger, 1995, 1998). In these paradigms, the responses of single neurons to a series of tone pips at different frequencies are recorded, and then one frequency is chosen to be the conditioned stimulus. A short time after the tone elicits the conditioned response (20–45 paired trials), the response of the neuron to the series of tone pips is again recorded. An example of a typical result is shown in figure 16.1 for neurons recorded in the secondary and ventral ectosylvian auditory cortical fields (Diamond and Weinberger, 1986). This figure is derived from the neurons that were the most sharply tuned for frequency. In most of these cells studied, there was an increase in the response to the tone paired with the foot shock (labeled 0 on the x -axis), with very little increase for other frequencies. This increase was reversed by a period of extinction, when the tone was presented in the absence of the foot shock for 20 trials (figure 16.1).

A similar result was shown in the guinea pig primary auditory cortex (Bakin and Weinberger, 1990), in which many neurons changed their frequency-tuning profile to respond best to the paired frequency (figure 16.2). In this paradigm, by choosing a paired frequency that was slightly different from the best frequency of the neuron, there was an increase in the response to the paired frequency and a parallel decrease in the response to the preconditioning best frequency, resulting in a shifted

FIGURE 16.1 Changes in the activity of auditory cortical neurons following a classical conditioning paradigm. The dark area denotes the percent change in the responses of the neurons as a function of the difference in frequency from the conditioned stimulus (CS) between the preconditioning and postconditioning conditions. The shaded area denotes the change in response between the preconditioning and postextinction conditions. Note that the greatest change occurred at the CS frequency. (Adapted from Diamond and Weinberger, 1986.)

tuning profile for the neuron. This type of change in the tuning profile of the single neuron has also been shown to last for up to eight weeks after training (Weinberger, Javid, and Lapin, 1993). These results indicate that there is an expansion of the representation of the paired frequency that parallels the acquisition of the conditioned response (see Weinberger, 1998). This is expected, given that the perception of the stimulus would surely change from one that has no behavioral relevance to one that signals that a foot shock is imminent.

Similar studies in the MGB have shown that the ventral division (MGBv), which contains the most sharply frequency-tuned neurons and is considered to be the major relay nucleus, does not show the same type of plasticity (Ryugo and Weinberger, 1978). However, the medial division (MGBm), which has more broadly tuned neurons and projects to the primary auditory cortex and other cortical areas, does show a type of plasticity very similar to that of the auditory cortex (Ryugo and Weinberger, 1978; Edeline and Weinberger, 1992). These results suggest that there are two parallel pathways within the auditory system, one which is largely immune to such conditioning effects, and the other which likely mediates the cortical plasticity observed following classical conditioning (for a more complete description of this topic see Weinberger, 1998).

Pharmacological studies suggest that acetylcholine (ACh) plays a key role in modulating the change in cortical

A. Single Unit Responses

B. Shift in Tuning Profile

FIGURE 16.2 Change in the response profile of a single auditory cortical neuron following conditioning. (A) Rasters and peristimulus time histograms (PSTHs) of the response to the best frequency of the neuron (0.75 kHz, left) and the frequency of the conditioned stimulus (2.5 kHz, right) before (top) and after (bottom) the conditioning protocol. (B) The complete tuning profile tested before (open circles) and after (closed squares) the conditioning protocol. Note that the postconditioning best frequency of this neuron is now at 2.5 kHz. This shift resulted from an increase in the response to the CS frequency and a decrease in the response to the previous best frequency. (Adapted from Weinberger, 1998.)

cal neuronal responsiveness. Application of ACh at the recording electrode can alter the response of the neuron to specific frequencies (McKenna, Ashe, and Weinberger, 1989). Iontophoresis of acetylcholine paired with

the presentation of a tone can result in an increase in the response of the neurons, similar to the effects seen with tone and shock pairings (Metherate and Weinberger, 1990). Similarly, direct stimulation of the nucleus basalis, which contains the neurons that release ACh in the cerebral cortex, shortly after the onset of a tone results in a similar enhancement of the neuronal response to the paired tone in both anesthetized animals (Bakin and Weinberger, 1996) and awake animals (Bjordahl, Dimyan, and Weinberger, 1998), and also results in a greater area of primary auditory cortex that responds to the paired tone (Kilgard and Merzenich, 1998). These data together indicate that (1) cortical responses can be altered over a very short time course and can be long-lasting, (2) these modifications presumably reflect a change in the perception of the stimulus, and (3) neuromodulatory elements facilitate, and may well be required, to effect such changes.

Cortical plasticity following operant conditioning

A direct test of the hypothesis that cortical representational plasticity reflects changes in perception and skill acquisition was conducted in the somatosensory cortex of adult owl monkeys. In the normal owl monkey, there is a topographically well-organized map of the contralateral hand in the primary somatosensory cortical area 3b. These experiments entailed training monkeys to perform a tactile discrimination task using only a small skin area of a single finger, measuring the improvement in performance at this task over the course of several weeks of training, and then relating this performance to the cortical representation of the small skin area used in the task.

Adult monkeys were trained to remove their hand from a tactile stimulator when they detected that the frequency of the stimulus increased from the standard of 20 Hz (Recanzone, Jenkins, et al., 1992). Initially, monkeys were only able to discriminate stimuli that were at least 5 Hz greater (i.e., 25 Hz). In the early phases of training, the thresholds decreased rapidly, followed by a longer and slower period of improvement during the subsequent weeks until these monkeys were ultimately able to discriminate differences in frequency of only 1–2 Hz. It is likely that the initial, rapid period of improvement is reflecting the ability of the monkeys to generalize to all stimulus frequencies and to develop the most effective “strategy” in performing the task (Recanzone, Jenkins, et al., 1992). When tested on an adjacent finger on two or three occasions throughout the period of extensive practice on a different finger, the thresholds reflected the rapid improvement component, but did not improve significantly during subsequent sessions (see figure 16.3).

A. Performance Improves with Training

B. Performance on Session 110

FIGURE 16.3 Improvement in performance measured during the performance of a tactile frequency discrimination task. (A) Schematic of the behavioral data where the threshold rapidly decreased during the first few training sessions, and was then followed by a much slower and progressive decrease in threshold with training. Open symbols denote the thresholds measured for the adjacent finger taken at three different time points over the course of the study. (B) Psychometric functions for both the trained (closed squares) and untrained (open squares) fingers taken the day before the electrophysiological experiment began. (Adapted from Recanzone, Jenkins, et al., 1992.)

The representation of the trained skin, as well as the same skin regions on nontrained fingers of the same and opposite hands, was then defined in cortical area 3b (Recanzone, Merzenich, et al., 1992). One striking difference was the increased area of representation of the trained skin when compared to similar, untrained skin surfaces (figure 16.4A). A second major difference was that the receptive fields on the trained skin surfaces were much larger than those on the untrained skin (figure 16.4B). A third major difference was in the responses of the cortical neurons to the same vibratory tactile stimulation that was used in the behavioral task (Recanzone, Merzenich, and Schreiner, 1992). As would be expected by the larger representation in gen-

D. Temporal Responses Predict Behavioral Thresholds

FIGURE 16.4 Changes in cortical representations of trained and untrained skin regions in monkeys trained at a tactile discrimination task. (A) The cortical area of representation of the trained (black) and adjacent, untrained (shaded) skin regions. (B) Representative receptive fields recorded for each of these fingers. The circles show the region of skin stimulated during the task for the trained (filled) and untrained (shaded) fingers. (A and B adapted from Recanzone, Merzenich, et al., 1992.) (C) Population cycle histograms taken from all locations that responded to stimulation of the trained and untrained skin surfaces in a single monkey. These cycle histograms were obtained by combining the action potentials for all stimulus

cycles excluding the first across all cortical locations. Bin size is 1 millisecond. The heavy line shows the responses to stimulation of the trained skin site; the thin line shows the responses to stimulation of the adjacent skin site. (D) Regression analysis between the measured behavioral threshold for both trained and untrained digits as a function of the predicted threshold based on differences in the population cycle histograms between the standard and test frequencies. The solid line shows the best-fit regression line; the dashed line shows perfect correlation. (C and D adapted from Recanzone, Merzenich, and Schreiner, 1992.)

eral, there was a greater number of neurons that responded to stimulation on the trained finger when compared to untrained monkeys or to other fingers on the same hand. Although the responses of the neurons at each cortical location were very similar to stimulation of the trained and untrained fingers, when the responses were pooled across the population of area 3b neurons, there was an increase in the temporal fidelity of the responses to these behaviorally relevant stimuli (figure 16.4C). This increased fidelity was strongly correlated with the behavioral performance of both trained and untrained digits (figure 16.4D). The large representations of the trained skin and the correlated activity across neurons to the same stimulus frequencies indicate that the population of cortical neurons became highly selective in their responses and responded synchronously to the same behaviorally relevant tactile input. As the monkey continued to practice the task over weeks of daily sessions, there was presumably an increase in this population encoding of the stimulus frequency, which resulted in better information on the stimulus frequency and therefore improved performance at the task.

The same result was subsequently found in the primary auditory cortex in monkeys trained to perform an acoustic frequency discrimination task (Recanzone, Schreiner, and Merzenich, 1993). Monkeys performing a similar type of behavioral task showed a progressive improvement in their ability to discriminate small differences in the frequency of sequentially presented acoustic stimuli (figure 16.5A). When the frequency representation was defined in these monkeys, there was a clear increase in the cortical area of representation of the behaviorally relevant stimuli (figure 16.5B, C) compared to controls that were either engaged in the task using a different standard frequency or were untrained in any task. This increased representation was similarly closely correlated with the improved performance and increased frequency discrimination acuity.

In both the somatosensory and auditory experiments, it was found that attention to either the tactile or auditory stimulus was required for the cortical changes to occur. In monkeys that received the same tactile stimulus but were performing the auditory discrimination task, changes were observed in the auditory cortex but not in the somatosensory cortex. Similarly, monkeys that received the same auditory stimuli while performing the tactile task showed changes only in the somatosensory cortex but not in the auditory cortex. These results strongly suggest that attending to the stimuli (and thereby activating neuromodulatory circuits such as ACh) is necessary to change the cortical representations, and presumably to effect a change in the percep-

Area of Responses in Motor Cortex with Training

FIGURE 16.6 Changes in motor cortical areas of representation with training. The number of successful pellet retrievals (heavy lines, left y-axis) is an indicator of the ability of the monkey to obtain the pellet. The area of representation of the relevant movements in the task (finger flexion and wrist extension) as a percent of the hand representation in the motor cortex is shown as the thin line and solid circles. This monkey went through five different phases of training, extinction, and reacquisition. The cortical area of representation of the relevant movements parallels the monkey's ability to perform the task. (Adapted from Nudo et al., 1996.)

tion, although this assumption was not tested in these animals.

Other studies in the motor cortex show a similar pattern of results. Motor cortical maps can be derived by electrically stimulating the deep cortical layers with small currents (10–30 μ A) and observing the elicited movements. Several studies on the motor cortex of squirrel monkeys indicate that the cortical representation of motor movements is related to the ability of the monkey to perform simple motor tasks. For example, there are differences in the organization of the hand representations in the primary motor cortex in individual monkeys, with the representation of the dominant hand being larger and more spatially complex than the representation of the nondominant hand (Nudo et al., 1992), presumably reflecting the greater use and dexterity of the dominant hand. Monkeys trained to make a set of specific movements, whether rotation about the wrist or movement of the wrist and fingers, had a greater representation of the practiced movements (Nudo et al., 1996). The changes in the cortical representations of these movements closely followed the behavioral ability of the monkey to retrieve the pellet, which is based primarily on the dexterity of the movement (figure 16.6). These data showed that the motor cortical representations are

plastic and can change over time in the adult animal and that these changes reflect the acquisition and degradation of the monkey's motor skills during the course of the experiments.

Cortical plasticity demonstrated in human subjects

Functional imaging techniques applied to human subjects have been valuable tools in investigating cortical plasticity in human subjects and indicate that cortical reorganization with training, as seen in the animal experiments, occurs in the human cortex as well. For example, humans who are practiced string players (violin, cello, or guitar) have greater cortical activation (based on MEG dipole strength) from stimulation on the fingertips of their left hands than people who do not play an instrument (Elbert et al., 1995).

Changes in cortical representations that relate to changes in the ability to perform a motor task have also been demonstrated in human subjects (Karni et al., 1995; see also Karni et al., 1998). In this study, the amount of activity in the motor cortex was defined using functional magnetic resonance imaging (fMRI) while the subjects made one of two matched, mirror-reversed sequenced finger movements (e.g., pinkie–middle–ring–index–pinkie). These subjects then practiced only one of these two sequences for 10–20 minutes each day. Over the course of several weeks the speed with which the sequences were performed increased, and the number of errors decreased. When the subjects were scanned again after training, there was more activation of primary motor cortex for the practiced sequence compared to the unpracticed sequence in each subject tested (figure 16.7). This result is predicted by the monkey experiments described earlier (Recanzone, Jenkins, et al., 1992; Recanzone, Merzenich, et al., 1992; Recanzone, Merzenich, and Schreiner, 1992; Recanzone, Schreiner, and Merzenich, 1993; Nudo et al., 1996), where the increased cortical areas of representation were correlated with an improvement in performance at a perceptual or motor task.

A second area of interest has focused on cortical plasticity in blind individuals who read braille. The previously discussed animal work predicts that these individuals would have increased representations of their braille-reading finger pads compared to either sighted or non-braille-reading controls. Evidence to support this hypothesis has been obtained using both scalp-evoked potentials and transcranial magnetic stimulation of the sensorimotor cortex of blind and control human subjects (Pascual-Leone and Torres, 1993; Pascual-Leone et al., 1993). These experiments have shown that there is an increase in the representation of the finger

Increased Response Area in Motor Cortex with Training

FIGURE 16.7 Motor cortex activation during a practiced and nonpracticed finger-tapping task. These data show the extent of motor cortex that was activated during the performance of the practiced sequenced finger-movement task (solid bars) compared to a similar but unpracticed sequence (stippled bars). Each subject showed an increase in the number of pixels activated within motor cortex for the practiced task. (Adapted from Karni et al., 1995.)

muscles most used during braille reading in motor cortex, and a greater activation of the sensorimotor cortex during stimulation of the fingertips used during braille reading. Interestingly, subjects who have been blind since infancy or early childhood also commonly have an activation of visual cortex during braille reading (Sadato et al., 1996) that does not occur in sighted individuals. This intriguing result suggests that the neurons in the cerebral cortex are not only capable of altering their responses within a given modality but can also change the modality of their responses if altered experiences occur early enough during development (see also chapter 7).

Experiments on human amputees further suggest that cortical plasticity can account for altered perceptions following the amputation. In many human amputee patients, there is a phenomenon known as the phantom limb (Henderson and Smyth, 1948; Cronholm, 1951; Haber, 1958) in which subjects clearly perceive their missing limb as still being attached, although they are cognitively fully aware that it no longer is. It had been suggested that the phantom limb was the result of the residual representation in the cortex of what used to respond to the arm input, following a “filling in” of the former hand representation by the face and arm representation, which is seen following amputations and deafferentation in monkeys (Merzenich et al., 1984; Pons et al., 1991). The human somatosensory cortex is functionally organized with a topography similar to that of the monkey; namely, the hand representation is bordered medially by the arm representation and laterally by the chin and jaw representation. Since there is no

longer any afferent drive from the missing limb, these cortical neurons would either come to respond to adjacent, intact body regions, or would remain silent as the deafferentation was too large to overcome (see Merzenich et al., 1984).

Functional imaging studies similarly indicate that the region formerly responding to the hand now responds to stimulation of the face (Yang et al., 1994; Elbert et al., 1994; see Ramachandran, 1993). The extent of this reorganization has been shown to be correlated with the amount of pain experienced in the phantom limb (Flor et al., 1995). In a second study (Birbaumer et al., 1997), injection of local anesthetic into the region near the amputation resulted in relief of phantom limb pain in half of the subjects tested. In those subjects that had pain relief, there was a reduction in the amount of apparent cortical reorganization following the injection of the local anesthetic. Interestingly, in the subjects that did not experience any pain relief or had not experienced phantom pain previously, there was no change in the cortical representations before and after the injection of the anesthetic. This result suggests that the amount of cortex that was reorganized from formerly representing the amputated arm and hand to representing the shoulder and face in some way contributes to the phantom pain or, conversely, that phantom pain in some way results in the altered cortical representation. It will be interesting to see how these two factors are related in future experiments.

Implications of cortical plasticity and changes in perception

This chapter has reviewed evidence that changes in perceptual acuity or motor skill are the result of changes in the cortical representations of the relevant sensory or motor aspects of the task. In each of the cases of cortical plasticity there is an increased representation of the relevant stimuli. Given that the size of the cerebral cortex is fixed in the adult, this result implies that the cortical representations of some sensory surfaces or movements have necessarily decreased in order to accommodate the greater representation of other sensory surfaces or movements. This relationship has been noted primarily in animal studies where there is a clear decrease in the cortical representation of adjacent skin surfaces in the somatosensory cortex (see Jenkins et al., 1990; Recanzone, Merzenich, et al., 1992), or the adjacent frequencies in the auditory cortex (Recanzone, Schreiner, and Merzenich, 1993) or different movement representations in the motor cortex (Nudo et al., 1996). Does this result then imply that there is a decrease in performance at some other task? The lim-

Perceptual Acuity Decreases Without Practice

A. Tactile Frequency Discrimination Task

B. Auditory Frequency Discrimination Task

FIGURE 16.8 Changes in perceptual performance as a function of practice. Data taken from one monkey that was trained at a tactile frequency discrimination task (A) taken from Recanzone, Jenkins, et al. (1992) and one trained at an auditory frequency discrimination task (B) taken from Recanzone, Schreiner, and Merzenich, (1993). In both cases, 1–2 weeks of testing on either a different skin surface or a different frequency (open circles) resulted in an increase in threshold for the previously practiced (solid circles) skin surface or auditory frequency.

ited data available suggest that this is indeed the case; performance at one task will change the cortical representations in favor of that task at the expense of some unpracticed task. For example, there was a progressive improvement in performance with training at both a tactile frequency discrimination task or an auditory discrimination task as described previously (figure 16.8; Recanzone, Jenkins, et al., 1992; Recanzone, Schreiner, and Merzenich, 1993). If the task is changed to test a different sensory surface, after the improvement in performance at the first, there is an improvement over time in

the performance for the new skin surface or frequency (open symbols, figure 16.8) and a corresponding decrease in performance at the previously trained skin surface or frequency (closed symbols, figure 16.8). A similar improvement and degradation in performance can be seen in motor tasks with a corresponding change in the cortical representation of the specific movements used in the task (figure 16.6; Nudo et al., 1996).

This is not a simple “zero sum” rule in which learning one thing will necessarily result in forgetting something else; rather, it is a simple reflection of the fact that performance at unpracticed tasks is degraded over time. There are clear anatomical and functional limits to the extent of cortical reorganization and the extent at which performance at a particular task can improve. I do not suggest that continued practice at a frequency discrimination task would ultimately cause only that narrow band of frequencies to be represented across the entire extent of primary auditory cortex at the expense of all other frequencies. The ability to process acoustic information is an important and behaviorally relevant task in most mammals, and there exists a driving force to maintain that ability in spite of a competing need to perform well at a specific task. Therefore, the cerebral cortex must be continuously modifying its central representations in a delicate balance to ensure that all of the behaviorally relevant and important information processing can take place. These dynamic processes are presumably continuing throughout life (e.g., see Merzenich et al., 1991, 1993) and likely account for the normal variability seen in cortical representations of different individuals of a species (Merzenich et al., 1987) and indeed the normal variations in abilities seen across individuals such as ourselves.

ACKNOWLEDGMENTS I would like to thank L. A. Krubitzer, N. M. Weinberger, M. L. Sutter, M. L. Phan, A. R. Tice, and J. A. Langston for helpful suggestions on previous versions of the manuscript. Funding provided in part by NIH grant DC-02371, the Klingenstein Fund, and the Sloan Foundation.

Introduction

J. ANTHONY MOVSHON
AND COLIN BLAKEMORE

In the context of modern cognitive science, it is easy to overlook the formidable tasks faced, and effortlessly mastered, by sensory mechanisms. The task of sensory systems is to provide a faithful representation of biologically relevant events in the external environment. In most cases, the raw signals transduced by receptors seem woefully inadequate to this task. These raw data are far removed from the complex structures in the world that give rise to them, in the same sense that the numerical values given to the pixels in a computer display are far removed from the true information that the display conveys. Yet our sensory systems all contrive, by subtle and complex calculation, to create efficient and informative representations of their perceptual worlds. These representations are at the same time enormously richer and enormously simpler than the basic measurements of light intensity, force, and chemical composition that support them. They are richer because they contain representations of objects, states, and events that are abstracted from the primitive sensory signals; they are simpler because they represent the distillation of the vast quantities of raw measurement information offered to the central nervous system by each sensory surface. To understand the full richness of sensory processing, we must appreciate both the volume of computation and the sophisticated deductions that give rise to our sensory experience. This section presents a variety of perspectives on the neural foundations of perception, derived from several different methods and several different sensory systems.

The most basic questions considered in this section concern the nature and meaning of the signals carried

by single sensory neurons and the maps and areas in which they live. The issues raised and addressed in chapters by Middlebrooks, Newsome, Parker, Shamma, Shapley, and Wandell have roots that extend back seven decades to the earliest recordings of sensory unit activity. How are sensory signals encoded by single neurons? How reliable and efficient is this encoding? How are single-neuron signals transformed and elaborated by successive levels of processing? How are different processing levels and areas represented in large-scale patterns of neural activity? Answers to these questions, and questions about the answers, continue to command the attention of those who study sensory systems. In favorable cases, remarkably sophisticated signals can be discerned in single neurons, and the efficient use of these signals by “higher” processes can in principle be used to reveal much of the information the organism uses to control behavior.

Beyond the basic encoding of the features of a stimulus, crucial questions arise concerning the perceptual context within which a particular element is perceived. These elemental representations must be blended and combined with information from other places and times in the sensory continuum to achieve a representation of the world's objects and events that separates them from the contexts in which they occur. The construction of this kind of elaborated representation is the concern of chapters by Adelson, Kersten, Lamme, and Singer. The task of understanding these representations uncovers a host of questions. How is perceptual context defined; what is “figure” and what is “ground”? How do widely separated elements of a sensory event get combined and articulated in sensory representations? How does the structure of the natural world influence the way in which it is perceived? What methods and mechanisms of statistical inference drive the transition from encoded elements to perceived events and objects?

Sensory processing cannot end with the encoding of a stimulus and its representation of objects and events in a context. The succession of events in a sensory analysis blend gradually from early stages that are purely stimulus-driven to later stages in which signals are modulated

by messages from other sensory systems, from memory systems, and from attentional systems. The task of uncovering the nature and role of these signals in higher areas is addressed in chapters by King, Maunsell, McCarthy, and Miyashita. How are different and separately computed kinds of information about the same sensory quality fused to yield fully formed representations of the world? How are those representations modulated by the behavioral state and needs of the animal, and by memories of other states, needs, and events? These issues occupy a no-man's-land between classically “sensory” processes and “cognitive” ones, and it is clear that this no-man's-land is in fact richly inhabited. It is, of course, inevitable that sensory signals will drive cognitive processing, but it is also clear that recurrent cognitive signals play an important role in sensory systems.

Perception is meaningless in the absence of action, and the final stage of understanding any perceptual process is to understand how it is used to initiate and orchestrate purposive behavior. This question is the concern of chapters by Doupe, Goodale, and Sejnowski. Sensorimotor integration is rapidly emerging as a crucial concern that spans the border between perceptual and motor systems. How do sensory representations become transformed into motor commands? How are sensory signals arising from actions of the observer distinguished from signals arising elsewhere in the world? How are motor sequences learned from sensory inputs? Is the information used for the control of action the same as, or different from, the information subserving “pure” perceptual processing?

The grand challenge of understanding perception requires that we be able to answer and address all the different phases of processing represented by the chapters in this section. The key issues in these chapters have wide relevance to cognitive processes, and spill over the traditional borders among sensation, perception, cognition, and action. Our ability to begin to address these questions with rigor and precision is producing a new and integrated view of the relations between perceptual processes and the other elements that form the neural basis of cognition.

17 Dynamics of Responses in Visual Cortex

ROBERT SHAPLEY AND DARIO RINGACH

ABSTRACT In this chapter we discuss our recent research on the dynamics of responses by single neurons in the primary visual cortex of macaque monkeys. Our experiments were designed to test ideas about the nature of cortical information processing. General principles of cortical information processing gleaned from this kind of research should, we hope, have wide applicability in the analysis of cortical function.

To understand vision properly, we need to understand how the cerebral cortex uses the signals that come to it from the lateral geniculate nucleus (LGN)—signals that ultimately derive from retinal signals evoked by patterns of light. This level of understanding would require a complete comprehension of the function of the cortex. A lot is known about neural connections in the visual cortex, the specificity of the input connections (Hubel and Wiesel, 1972; Blasdel and Lund, 1983; Lachica, Beck, and Casagrande, 1992; Yoshioka, Levitt, and Lund, 1994), and the wealth of feedback and lateral connections within V1 and between V1 and other areas (Rockland and Lund, 1983; Gilbert and Wiesel, 1983; Lund, 1988; Lund, Yoshioka, and Levitt, 1993). But why is the cerebral cortex organized in this way—what is the purpose of building a machine with this specific architecture? That question we cannot answer yet. Even while we focus on difficult immediate problems, we should bear this major question in mind.

Orientation tuning and cortical function

One of the crucial facts about what happens at the cortex is the transformation from spatially isotropic to orientation tuned elements (studied first in cat visual cortex by Hubel and Wiesel, 1962; then in monkey cortex by, among others, Hubel and Wiesel, 1968; Schiller, Finlay, and Volman, 1976; De Valois, Yund, and Hepler, 1982). Prior to the cortex, in single neurons in the retina and LGN, there is weak or no orientation selectivity. Some authors have emphasized the ellipticity of the LGN receptive fields as a possible source of orientation bias in the cortex (Shou and Leventhal, 1989; Smith et al., 1990; Vidyasagar, 1992). However, direct comparison of the amount of orientation tuning expected from single

LGN inputs to the amount of orientation tuning seen in cortical cells reveals that the contribution of orientation tuning in individual LGN neurons is a relatively small part of the story (e.g., see Reid and Alonso, 1995). It has been thought from the time of its discovery that orientation tuning of single visual neurons, as an emergent property in visual cortex, must be an important clue to how the cortex works and why it is built the way it is. But a comprehensive and satisfactory explanation of this phenomenon has resisted visual neuroscience even now. Indicative of a resurgence of interest in this problem, several opinions about recent data have been expressed in recent review articles (Das, 1996; Reid and Alonso, 1996; Sompolinsky and Shapley, 1997). The reviews of Das and Reid and Alonso emphasized the significance of the experimental evidence by Ferster and colleagues—data indicating that the LGN input to cortical cells is highly tuned for orientation (Ferster, Chung, and Wheat, 1996). Sompolinsky and Shapley's paper, on the contrary, reviewed the experimental evidence and theoretical arguments for the importance of corticocortical connections in orientation selectivity. The motivation of our work on cortical dynamics is to offer a fresh experimental approach to this problem (Ringach, Hawken, and Shapley, 1997).

From the time of its publication, Hubel and Wiesel's (1962) feedforward model has been a dominant idea in this field. This model is simple and has the great virtue of being explicit and implementable. It involves the addition of signals from LGN cells that are aligned in a row along the long axis of the receptive field of the orientationally selective neuron. For the often-encountered edge-sensitive orientation tuned cells, Hubel and Wiesel postulated that a row of ON cells from the LGN would provide excitatory input and an adjacent parallel row of OFF cells would provide excitation in response to the opposite sign of contrast. There is some indirect support for this kind of neural architecture in the ferret visual cortex (Chapman, Zahs, and Stryker, 1991), and more direct support from recent dual recordings in LGN and cortex in the cat (Reid and Alonso, 1995). The meaning of the Chapman results in ferret cortex is problematic because their later work on the orientation tuning of cortical cells in the input layer of ferret visual cortex indicates that these cells are very broadly tuned

for orientation (Chapman and Stryker, 1993); more properly, one would call layer 4 neurons in ferret visual cortex orientation-biased, not really orientation-tuned. Thus not all of the ferret LGN cells, whose synaptic terminations form long rows of aligned visual inputs located near a cortical layer 4 cell, make contact with that individual cortical cell—otherwise the cortical neuron would be much more tuned for orientation than it is. This means that the earlier paper by Chapman and colleagues (1991), the paper usually cited as strong support for the Hubel–Wiesel model, is not persuasive. However, the experimental result on orientation tuning in cat cortex after cortical cooling (Ferster, Chung, and Wheat, 1996) is an important result that indicates that the collective thalamic input to a cortical neuron is tuned for orientation.

Moreover, there is a serious problem with the 1962 Hubel–Wiesel model: It predicts too little orientation selectivity, and it also has as its consequence that none of the cortical cells would be “simple” cells according to Hubel and Wiesel’s original definition in that same classic paper. The reason for these problems has been known for a long time. The LGN cells clip at 0 spikes/s even at fairly low stimulus contrast, and therefore would act like nonlinear subunits as inputs to their cortical targets (Palmer and Davis, 1981; Tolhurst and Dean, 1990; Shapley, 1994). The response of the Hubel–Wiesel model would then be the sum of all these rectifying LGN receptive fields. Under these circumstances, there would be no reason for the model to have zero response at 90 degrees from the optimal orientation; in fact, for most reasonable choices of receptive field shape, one would predict a response at the perpendicular orientation at least half as strong as that at peak.

The Hubel–Wiesel model also predicts a qualitative response feature that is *not* observed—a change in the pattern of response to a drifting grating as a function of orientation. The response should be synchronized, at the drift frequency, at the optimum orientation parallel to the long axis of the LGN row. But it should be mainly elevated spike rate with little or no modulation when the stimulus is at the orthogonal orientation. The pattern of response at the optimal orientation, synchronous with the bars of a grating pattern, would be characteristic of what are called “simple” cells, while the elevated discharge rate at the orthogonal-to-optimal orientation—dominated as it is by the nonlinear, thresholded, LGN input—would be termed a response characteristic of “complex” cells.

The dependence of orientation tuning bandwidth on stimulus contrast is another, third, consequence of the Hubel–Wiesel model that is not observed in cortical cells. When contrast is low, the Hubel–Wiesel model

predicts sharper orientation tuning than when contrast is high because the LGN nonlinearity would cause much less broadening of the input at low contrast, and the cortical cell’s threshold would sharpen the tuning considerably in the cortex when the summed input is relatively weak, as it is at low contrast. None of the three predictions of the Hubel–Wiesel model discussed here is observed in real cortical cells: Orientationally tuned cortical simple cells respond little or not at all at 90° from peak orientation, the response of a simple cell is synchronized to the input drift rate at all orientations where there is a response, and there is approximate contrast invariance of orientation tuning. Real (and fairly typical) data from a representative simple cell in cat cortex are displayed in figure 17.1, from the work of Sclar and Freeman (1982). This figure shows orientation tuning curves measured at four different contrasts, from low to fairly high contrast. The narrow tuning and relative independence of tuning with contrast are notable features of this figure.

To correct the problems of the Hubel–Wiesel model, one can add opponent inhibition as in the “push-pull”

Cat V1 simple cell spike responses
Orientation tuning and contrast

FIGURE 17.1 Orientation tuning in a simple cell from cat V1 at four different contrasts. These are steady-state data collected when a cat simple cell was driven by a single drifting sine grating at the optimal spatial frequency and temporal frequency. Four different contrasts generated the four different curves. The height of the curves is dependent on contrast, but the shape of the curve is relatively invariant with contrast. This cat cortical neuron is about average in the sharpness of its orientation tuning.

model (Palmer and Davis, 1981; Tolhurst and Dean, 1990; Ferster, 1988, 1992). But one must suppose that this inhibition is through cortical interneurons rather than direct from the thalamic afferents. The reason for this qualification is the dogma that there is no direct thalamocortical inhibition, only excitation (see Lund, 1988). Inhibition would have to be mediated through cortical inhibitory interneurons. However, there is a problem with the push-pull model, too. It predicts that there ought to be excitatory *and* inhibitory input when the stimulus is orthogonal to the long axis of the receptive field, with inhibition erasing the excitation. However, intracellular recording in cat cortex revealed that excitatory *and* inhibitory input was minimal at the orthogonal orientation (Ferster, 1986, 1992). So there seem to be problems accounting for major qualitative properties of orientation tuning only in terms of thalamic excitatory and inhibitory inputs, though there is good evidence that these inputs are organized to contribute to orientation tuning to some extent. This is only a problem if orientation tuning is supposed to occur at the first stage in the cortex, as in the Hubel–Wiesel model. Of course, there is the possibility that sharp orientation tuning emerges only in layers of the cortex above and below layer 4, layers of cortical cells in which corticocortical interactions are the major source of orientation tuning. This is in fact what we observed in the monkey striate cortex and will show below.

Experimental work about the importance of corticocortical interactions in causing orientation tuning has proceeded in a different direction. Initially, Sillito's (1975) experiments with bicuculline suggested that intracortical inhibition might be necessary for orientation tuning. But those experiments are confounded by ceiling effects, and the direct experiments of Nelson and colleagues (1994) blocking inhibition intracellularly prove that inhibition onto a single neuron is not necessary for that neuron to be orientation tuned. However, the role of intracortical inhibition as a factor in cortical orientation tuning has been supported by the work of A. B. Bonds and collaborators in their studies of interactions between stimuli at different orientations (Bonds, 1989), of the effects of blocking activity in infragranular layers (Allison, Pflieger, and Bonds, 1995), and of the effects of GABA on orientation selectivity (Allison, Casagrande, and Bonds, 1995). A completely different result supports the idea that corticocortical effects are important—namely, the contrast-invariance of orientation tuning in the results of Sclar and Freeman (1982) and Skottun and collaborators (1987). As described previously in connection with figure 17.1, without corticocortical interaction, one would expect orientation tuning to broaden at high contrasts. That corticocortical recurrent

connections may yield contrast invariant orientation tuning is one of the main conclusions of the theoretical work of Ben-Yishai, Bar-Or, and Sompolinsky (1995), as discussed below.

The idea that corticocortical feedback plays a crucial role in orientation tuning has been put forward most forcefully by theorists of brain function. There are three new papers that make the case for corticocortical feedback. Each emphasizes in its own way the importance of recurrent excitation as well as inhibition. One is the paper by Somers, Nelson, and Sur (1995) which puts forward a complex computational model for orientation tuning. Another is the paper by Douglas and collaborators (1995) which argues for the importance of recurrent excitation in cortical circuits, and its role in orientation tuning as an example. A third paper in this genre is the work of Ben-Yishai, Bar-Or, and Sompolinsky (1995). Ben-Yishai and colleagues offer an analytical model from which they make several qualitative and quantitative predictions. The most important prediction is that with feedforward models you cannot predict contrast invariance of orientation tuning without postulating some intracortical mechanism like a contrast gain control. However, their feedback model with recurrent excitation and inhibition will exhibit contrast invariance. In recent simulations with a model that shares some of the features of the Ben-Yishai model and the Somers model, M. Pugh and colleagues observed that feedback models generate secondary peaks in the orientation tuning curves at 90 degrees away from the optimal orientation, at times after the main peak emerges, and that orientation tuning exhibits some evolution or sharpening of tuning with time (Pugh et al., in press). These features are reminiscent of what can be expected from recurrent lateral inhibitory networks (Ratliff, 1965) because secondary peaks and troughs in activity emerge naturally due to recurrent interaction, and different dynamics of excitation and inhibition in recurrent networks can cause time evolution of tuning. As we report below, we have observed features such as secondary peaks and troughs in the orientation domain for some monkey striate cortical neurons, so we believe that at this point we should take the feedback models seriously. This is the starting point for the research described in detail below on the dynamics of orientation tuning in visual cortex. To make clear the structural differences between a feedforward model, such as the Hubel–Wiesel model, and such feedback models as those of Somers and Ben-Yishai, we offer figure 17.2, a cartoon sketch (from Somers, Nelson, and Sur, 1995) of different cortical models that have been used to explain orientation tuning.

Before embarking on new methods and new results, let us reflect on why it matters whether feedforward

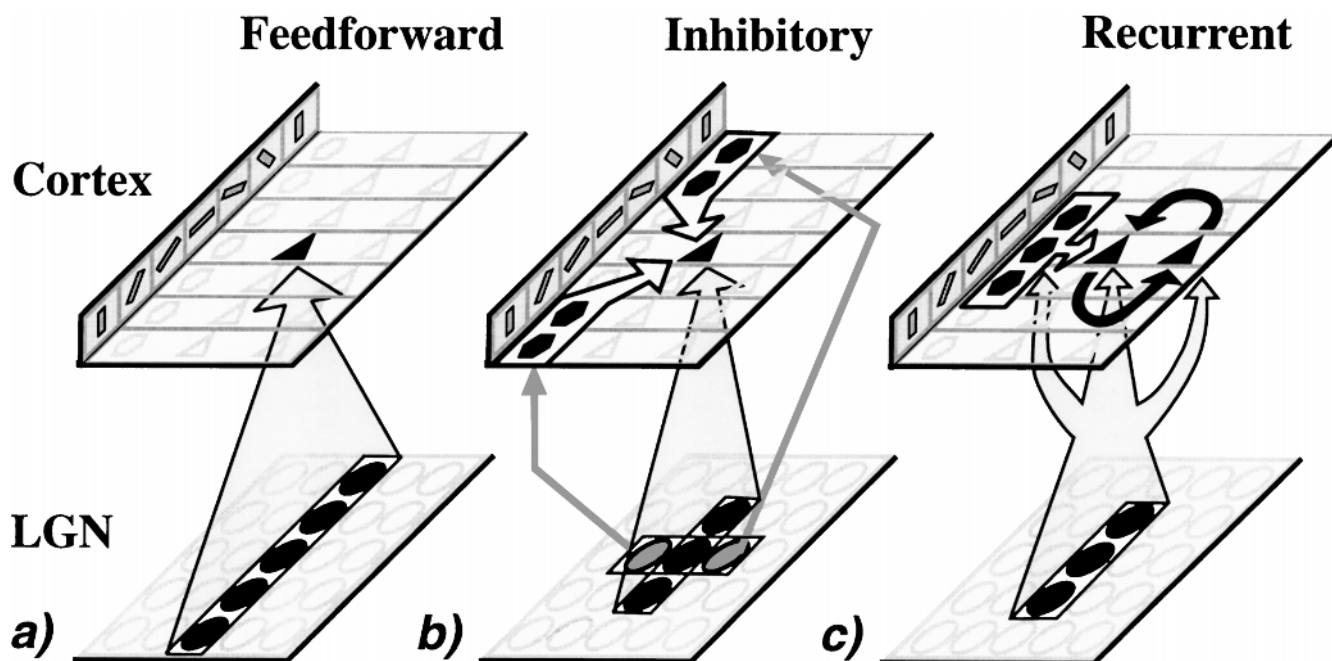

FIGURE 17.2 Sketch of different models for cortical orientation selectivity. At the cortical level, hexagonal shapes stand for inhibitory neurons and triangular shapes stand for excitatory neurons. The LGN cell are depicted as the circular shapes at the LGN level in the models. (a) Feedforward. All first-order cortical cells receive input from a row of LGN cells aligned in space. (b) In inhibitory models, there is inhibitory input from orientation-tuned cortical neurons, indicated by the outlined

white arrows. (c) Recurrent excitatory and inhibitory feedback models have both corticocortical inhibition (white arrows) and corticocortical excitation (black arrows) impinging on all cortical cells. These corticocortical interactions are supposed to greatly sharpen a broadly tuned input from LGN (indicated by the shorter row of aligned LGN cells). (From Somers, Nelson, and Sur, 1995.)

convergence or lateral cortical interactions generates orientation selectivity. The difference between these two explanations matters a lot for our conception of cerebral cortical function. If orientation selectivity is due mainly to the specific pattern of convergence of LGN afferents, this would mean that a fundamental function of the visual cortex arises from the feedforward filtering of the sensory input, supporting the view of cortical processing as implementing a hierarchy of feedforward transformations. However, if intracortical circuitry plays an important role in orientation tuning, it implies that intracortical interactions shape the nature of the internal representations of the external world that form in the cortex.

Orientation tuning dynamics

Knowing whether the sharpness of orientation tuning changes during the time course of the cell's response is central for the understanding of the mechanism for orientation selectivity. Unfortunately, this issue has been controversial. The sharpening of the intracellular potential of cortical neurons with time, observed by Pei and colleagues (1994), suggests that the extracellular responses should show a similar effect. However, Cele-

brini and collaborators (1993) found the opposite result, that orientation selectivity is fully developed at the very start of the extracellularly recorded spike train response in virtually all the recorded cells in V1 of awake monkeys. We sought to investigate this crucial question with a new methodology.

Reverse correlation in the orientation domain was used to measure the time evolution of orientation tuning. The stimulus generation and the procedure used in the data analysis are described first. We then discuss the method's practical advantages.

For each cell, a set S of sinusoidal gratings of a fixed spatial frequency (optimal for the cell) and contrast (in the range 80–99%) but different orientations and spatial phases was generated and stored in the computer's memory. The orientation domain was sampled in equal steps ranging between 3° and 12° . For most of the cells reported here the angular resolution was fixed at 10° . For each orientation, sinusoidal gratings at four or eight spatial phases were included in the set. The spatial phases were equally spaced and covered the entire 360° range. In a typical experiment, the total number of images required was 144 (18 orientations times 8 spatial phases).

The stimulus was generated by randomly selecting, at each video refresh time, a new image from S (with replacement). Unless otherwise noted this was done at a rate of 60 frames/s. The stimulus can be described as a very rapid sequence of gratings with random orientations and spatial phases. Stimulus segments were presented in 30-s trials with interstimulus intervals of approximately 1–2 s. Usually, 30 trials were presented to each cell, making the total experiment time about 15 m. The specific image sequence used in each trial was saved by the computer. During the stimulation period, action potentials were recorded extracellularly and time-stamped by the data acquisition system. In the experiments reported here, the size of the stimulation patch was large compared to the “classical receptive field” size of the cell defined by the peak of an area tuning curve obtained using circular stimulus patches of varying radii. The radius of the circular stimulus patch used in the experiments was between 2 and 6 times the optimal radius. This resulted on an average stimulus size of approximately 4° in diameter. The receptive field of the cell was centered at the middle of the stimulus. Therefore, both the classical receptive field of the cell and its surround were stimulated. This was done so as to include all the functional processes that would contribute visual inputs to cortical neurons and affect their orientation selectivity. Thus, it should be clear that inputs from the surround may contribute to the dynamic responses reported below.

The time course of orientation selectivity was determined according to the following algorithm. First, an array of counters corresponding to each of the orientations present in the stimulus was zeroed. A fixed value of a time-delay parameter τ was selected. For each nerve impulse recorded we went back τ ms in time and obtained the orientation of the grating that was present at that moment in the image sequence. The counter corresponding to that orientation was incremented by 1. Responses at a given orientation but different spatial phases were pooled. Let us denote by $N(\theta)$ the number of counts in the bin indexed by the orientation angle θ , and by M the total number of spikes collected. Notice that the sum of all spikes in the different orientation bins should equal the total number of spikes collected. We define

$$p(\theta, \tau) = N(\theta) / M$$

where $p(\theta, \tau)$ gives the empirical probability (or relative frequency) that an orientation θ was present in the stimulus image sequence τ ms before a nerve impulse was generated by the cell. For a fixed value of τ , $p(\theta, \tau)$ is a probability distribution on the orientation angles present in the stimulus set.

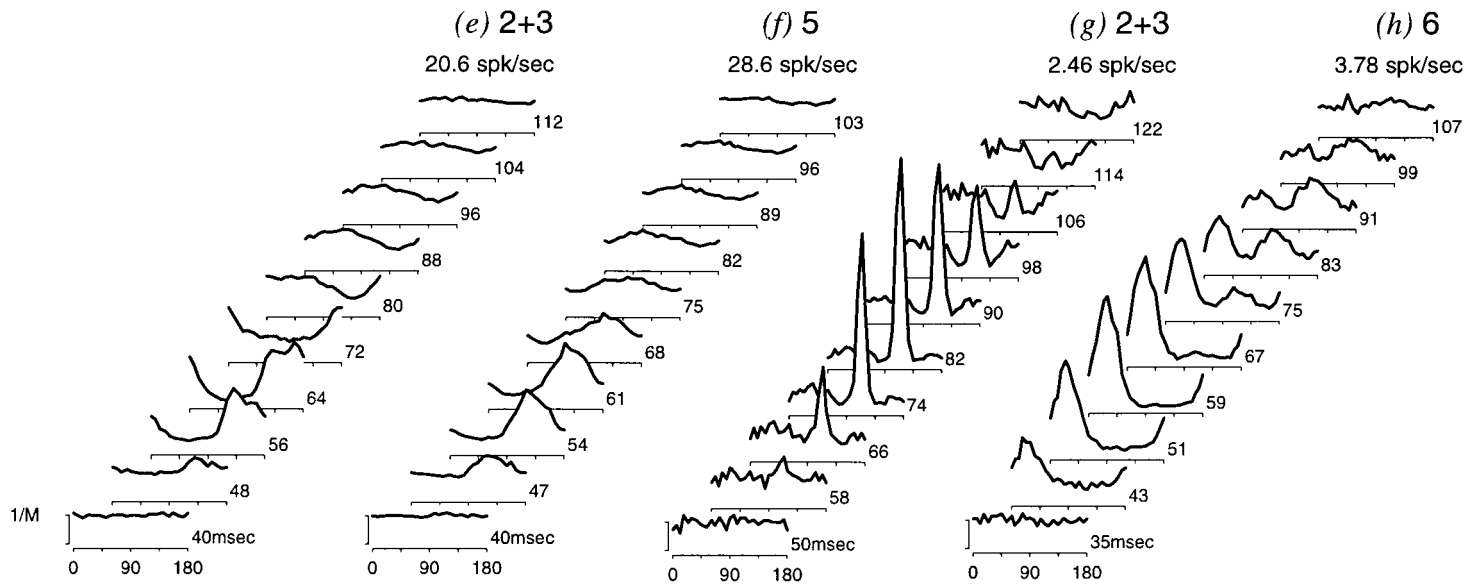

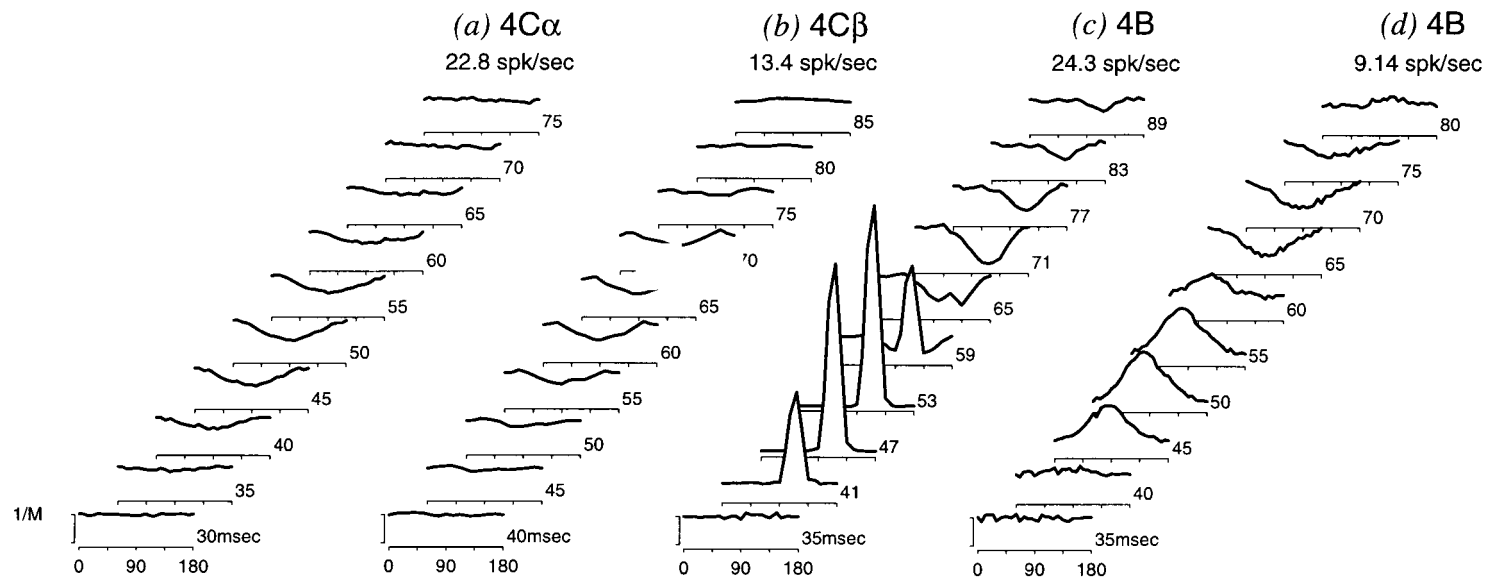

It is worth considering how many data go into the calculations of $p(\theta, \tau)$. We usually run the orientation dy-

namics data collection for 15 minutes—i.e., 900 seconds—or 54,000 stimulus images presented to the monkey. For a typical run where we are using 5° angular resolution, there are 375 presentations of each image to average over because there are 36 angles times 4 spatial phases, or 144 distinct images, in the image set. Another way of looking at it is if a typical cortical neuron fires on the average 5 spikes/s to the image sequence, then the reverse correlation will average over 4500 spikes. Therefore, we can obtain quite smooth, accurate orientation tuning curves.

We can study the dynamics of orientation tuning by studying $p(\theta, \tau)$. For $\tau = 0$, for example, we don't expect to see any influence of the input on the output spike train because visual integration and delay in the retina and subcortical visual pathway are too slow for us to observe anything happening in the cortex. Therefore, $p(\theta, 0)$ would be a flat function with respect to orientation. Similarly, for very long τ , we also expect to see a flat distribution of $p(\theta, \tau)$; this is because cells have finite memory. For intermediate values of τ , we expect to see a smooth peaked distribution which represents the preference of the cell for particular orientations. Using these techniques, we have done experiments on dynamics of orientation tuning in different layers of macaque monkey visual cortex (V1). The results indicate two main patterns of dynamics: unimodal and multimodal. Unimodal dynamics means that the response, after a delay, simply increases and relaxes monotonically. We have observed multimodal dynamics of several types: (1) rebound responses, where the response at and around the peak orientation reverses its relative probability compared to the baseline and actually becomes a trough of probability 20–50 ms after the time it was a peak; (2) time evolution (sharpening with time) of orientation tuning; or (3) transient peaks of activity at off-optimal orientation, most often at 90° from the peak. In none of these cases is the orientation tuning function separable (factorable) in the two dimensions of orientation and time.

The method we used allows us to measure orientation tuning when the test stimuli are embedded within a rich stimulus set of temporally adjacent stimuli. We studied neurons in all layers of macaque V1, keeping track of their locations through standard methods of track reconstruction. In these early experiments, we used only high-contrast stimuli in order to get strong responses (contrast $>90\%$). In these experiments the area of the stimulus was chosen to be 4–36 times bigger than that of the conventional receptive field of the neuron under study. Thus our stimuli covered the conventional receptive field as well as the “silent surround.” This is what most researchers who have studied orientation tuning with conventional stimuli have done previously (see, for

$r_t(\theta)$ 1/deg

Orientation (deg)

example, De Valois, Yund, and Hepler, 1982; Celebrini et al., 1993; among others). It would be very interesting to study the dependence of orientation tuning sharpness and dynamics on stimulus area, and we have begun such a study.

Results

The major findings of our studies are as follows: (1) There is a very strong laminar dependence of orientation tuning sharpness. (2) There is an equally impressive dependence of orientation tuning dynamics on laminar location. (3) The pattern of the dynamics of sharply tuned cells in the output layers of V1 is consistent with a two-mechanism model in which an early, orientation-tuned excitatory signal is summed with a later, somewhat more broadly tuned, orientation-tuned inhibitory signal.

Most cells in the input layers 4C α and β have simple, unimodal dynamics and are relatively broadly tuned for orientation. By unimodal dynamics we mean that, after a time delay, the response has a single peak in time and, after the peak, simply relaxes back to baseline. However, cells in layers 2, 3, 4B, 5, and 6 showed multimodal dynamics: rebound responses, sharpening of the orientation tuning with time, and/or transient peaks of activity at off-optimal orientation. Figure 17.3 (from the results of Ringach, Hawken, and Shapley, 1997) illustrates unimodal dynamics in 4C neurons' responses and multimodal dynamics in the response of neurons of the output layers 2, 3, 4B, 5, and 6. We found that these neurons with multimodal dynamics are usually much more sharply tuned in orientation.

Some of the data that suggest the two-mechanism model are given in figure 17.3. It shows orientation tun-

ing functions, derived from reverse correlation measurements, for two neurons (labeled c and d) in macaque V1 layer 4B. Note that in layer 4B, which is located just above layer 4C α , there is already evidence for complex interactions in the orientation domain: Rebound inhibition in both 4B cells can be observed around the 65-ms delay; and in cell c, there is clear evidence for flanking inhibition around the peak at 55 ms. In cell d's response, there is an especially clear indication of an elevated response orthogonal to the main peak, at a later time, at 65 ms in this case. In both these representative examples, there is a clear suppression, peaking at the formerly preferred orientation, at about 20 ms after the peak excitatory signal.

Implications

These results indicate that lateral interaction in the orientation domain is prevalent in striate cortex. The nature of this interaction is not yet understood. But the sombrero shapes of the orientation tuning distributions—so evident in cell c in figure 17.3 at 55 ms, for instance—suggest that we must consider recurrent or feedback inhibitory mechanisms in a model for the cortex. These sombrero-like distributions in orientation resemble the difference-of-Gaussian sensitivity distributions of center-surround receptive fields in the spatial dimension, and are predicted by feedback models of cortex (see, for instance, Somers, Nelson, and Sur, 1995; Ben-Yishai, Bar-Or, and Sompolinsky, 1995; Carandini and Ringach, 1997).

This work has implications about the validity of the receptive-field idea as a way of understanding cortical function. The implication is that lateral interactions in the cortex shape many aspects of cellular functions. Support for this view comes from quite a lot of work using a very different paradigm—the study of cortical visual interactions across space, also known as “contextual effects.” This includes the work on center-surround interactions (reviewed by Allman, 1985), on orientation contrast (Knierim and van Essen, 1992; Sillito et al., 1995; Levitt and Lund, 1997), and on figure-ground effects (e.g., Lamme, 1995; Zipser, Lamme, and Schiller, 1996). There is also the recent work by Bullier and colleagues (reviewed in Salin and Bullier, 1995) that indicates the importance of feedback connections from extrastriate areas into V1. This body of work suggests that the cells in the primary visual cortex are influenced by lateral and feedback interactions in a very significant way, much more so than was imagined when the receptive field concept was first applied to cortex. In perception of natural scenes, even more than in laboratory experiments on simplified stimuli, the effects of context

FIGURE 17.3 Reverse correlation measurements of the time evolution of orientation tuning in macaque V1 neurons from all layers of striate cortex. The vertical scale is probability, the horizontal axis is orientation angle, and each graph in the perspective plot is for a different time offset τ . The orientation distributions before the first perspective plot and after the last perspective plot are all flat across orientation. Cell (a) is from 4C α , and cell (b) is from 4C β ; cells (c) and (d) are two different cells from layer 4B, and they illustrate the types of multimodal dynamics seen outside the input layers. Cell (e) is from layer 2/3; cell (f) is a cell from layer 5 that illustrates the change in preferred orientation tuning with time; cell (g) is an especially sharply tuned cell from 2/3 that has very strong flank suppression with a clear sombrero-like orientation distribution for times between 82 and 114 ms. Cell (h) is a layer-6 cell that has a clear multi-peaked orientation tuning curve at time delays of 82–91 ms. M is the number of images shown, so $1/M$ is the uniform probability expected when there is no orientation response. (These data are redrawn from Ringach, Hawken, and Shapley, 1997)

may play an important role in visual cortical cell responses. This must be quantified in future experiments.

With respect to the visual function of V1 cortex, this work makes it clear that the conventional view—that the cortex is a filter bank of static filters tuned to spatial frequencies and orientations in small regions in the visual environment—is a distortion of the true function of the cortex. Rather, when we use dynamic stimuli to probe the function of the cortical network, we see that cortical cells are alive with possibility. They exhibit near-neighbor inhibition that is slow, and near-neighbor excitation that is very fast. And they reveal dynamic changes in their orientation selectivity, with many neurons sharpening their tuning with time, but very rapidly. What is most striking is that, because of the delayed inhibition clearly evident in the neurons from layer 4B in figure 17.3, there is a marked change in the orientation preference of the neurons during the time evolution of their responses. Early in the response, there is a peak at the same orientation, approximately, as the peak of the steady-state tuning curve measured with conventional drifting stimuli like gratings or bars. However, later in the response, usually about 20 ms later, there is a rapid shift to an orientation preference orthogonal to the initial peak (because the late inhibition is greatest at the early peak orientation). We need to consider the importance of this time variation in preferred orientation for the visual function of the neurons in the cortex. What it means, we think, is that the optimal stimulus for such neurons may not be a line or a grating; rather, it is a time-varying, oriented boundary which is oriented at the initial peak orientation first and then rapidly switches to the orthogonal. What sorts of stimuli are these? Two possibilities occur to us: curved boundaries, and 2D features like corners or junctions. As the eye moves along a curved boundary, the orientation of a boundary that falls on a particular region of the eye, and hence the cortex, changes substantially and systematically. This means that it is the kind of dynamic change of orientation that might be particularly effective in stimulating cortical neurons. The effect of a corner or other 2D junctions could be even more effective because the boundaries at a corner often abruptly jump through 90° of orientation. This would be a most effective stimulus for many cells in layer 4B and in layers 2/3, which project to V2 and thence to many visual areas of the brain. Such speculations will need to be checked with experiments in the coming years. But it is clear that these and other new experiments have completely changed our view of the rich possibilities of information processing in primary visual cortex. And this also offers hope that the cortical mechanisms uncovered in V1 may be useful in comprehending the function of the cerebral cortex as a whole.

ACKNOWLEDGMENTS Our experiments were done in collaboration with Michael Hawken, Ferenc Mechler, Michael Sceniak, and Elizabeth Johnson, and we are very grateful to them for their help and their useful comments. The experimental work was supported by grants from the U.S. National Eye Institute, the U.S. National Science Foundation, and the Sloan Foundation.

18 Binocular Neurons and the Perception of Depth

ANDREW J. PARKER, BRUCE G. CUMMING, AND JON V. DODD

ABSTRACT Understanding the links between perception and the activity of single neurons would be a major achievement for cognitive neuroscience. The perception of stereoscopic depth through binocular vision provides a number of opportunities for studying these links. We present the results of recent experiments in the striate visual cortex (V1) and extrastriate visual areas (V2 and V5) that illustrate progress in investigating these issues.

The prevailing paradigm in cognitive neuroscience holds that activity within certain neurons will lead to the perception of a particular quality, such as color, motion, or pitch. It is widely assumed that the critical population of neurons resides within the cerebral cortex. Activity is rather broadly conceived here, so that the pattern of activity across a population of neurons (Recanzone, Merzenich, and Schreiner, 1992) or the presence of characteristic temporal sequences of action potentials (Singer and Gray, 1995) is within the scope of this term. The more specific issues that arise from supposing that the activity within *single neurons* is critical have been discussed elsewhere (Barlow, 1972; Parker and Newsome, 1998). Briefly, the properties of candidate neurons should account for the characteristic features of perceptual performance; loss of the relevant neurons should lead to some behaviorally measurable defect in perception; artificial stimulation of the neurons electrically or chemically should alter behavioral measures of perception; and the trial-to-trial fluctuations in neuronal performance should have measurable consequences for behavioral performance.

The work presented here falls within this prevailing paradigm. Nonetheless, it is worth a pause to consider alternatives. Essentially, the relevant level of analysis would be either more “fine-grained” or more “coarse-grained” than the level of single neurons. More “fine-grained” would mean examining subcellular processes, perhaps from the level of dendrites down to single ion channels or other molecular processes within the neuron

and its immediate extracellular environment. More “coarse-grained” would mean examining the pooled signal from spatially neighboring neurons by means such as optical imaging, PET, or fMRI or by measuring the signal at several points within a circuit of neurons (Abeles, 1991). Neither of these alternatives is self-evidently incoherent as a theory of how the nervous system could work. Nonetheless, each alternative would eventually need to arrange for some output in the axons that travel from one cortical region to another (and eventually to the axons of motor neurons). At least in this respect, the signals provided by single neurons are crucial.

Binocular vision

Binocular vision is an excellent model system for investigating the links between neuronal activity and perception. Unlike perceptual phenomena that depend primarily on peripheral mechanisms (for example, the spectral sensitivity curve of scotopic vision), binocular vision requires the central combination of information from the two retinas. This requirement emphasizes the significance of signals at a cortical level. Binocular vision can also be probed with stimuli such as random-dot stereograms that ensure that the observer must use the stereoscopic system to extract the required information (Julesz, 1971). Stereoscopic vision has been studied intensively at the psychophysical and computational level (Poggio and Poggio, 1984): hence, stereo vision is known to exhibit a diverse and characteristic set of phenomena that are well suited for study at the neurophysiological level.

In our view, binocular vision has just about the right degree of complexity for studying the links between neurophysiology and perception. On one hand, simpler systems, such as the photoreceptors and ganglion cells in the retina, have already been examined, and, in any case, they tell us little about the essential cortical processes involved in the act of vision. On the other hand, given our present level of understanding, the study of more complex perceptual phenomena, such as object recognition, leads inevitably to an insufficiently precise specification of the perceptual task facing the observer.

Overview of this chapter

The experimental work presented in this chapter divides into two parts. The first part examines the responses of binocular neurons in the striate visual cortex (V1). The aim is to determine whether some of the characteristic features of the psychophysics of stereoscopic vision can be explained by reference to the properties of V1 neurons. The answer is negative, a result that forces us to look outside V1 in search of an explanation for these characteristics. There is a widespread distribution of disparity-selective neurons in several extrastriate cortical areas. In the second part, we examine findings in two of these extrastriate cortical areas, V2 and V5(MT). Area V2 has been repeatedly implicated as having a special role in binocular stereopsis. By contrast, V5(MT) has been most associated with a role in processing visual motion. Recent evidence implies that these neurons are also responsible for signaling some aspects of binocular depth. Finally, we discuss the currently popular idea that feedback connections from extrastriate cortical areas to V1 might signal perceptually relevant information (see Lamme and Spekreijse, chapter 19 of this volume).

Binocular neurons in V1

The studies in V1 arise out of comparisons between characteristic psychophysical properties of the stereoscopic system and the properties of disparity-selective cortical neurons. Each study reveals a discrepancy between the way in which stereo depth is perceived and how neurons in V1 respond, even those that are highly tuned for binocular disparity. By itself an individual discrepancy of this kind would not mean much. But as it turns out, all four discrepancies consistently support a simpler explanation of the behavior of V1 neurons: namely, that they are acting as a preliminary binocular matching system, with characteristics close to that of a pair of spatial filters that process the output of the left and right retinas and provide for a simple binocular combination of this information.

We will deal with the specific predictions of the binocular filtering model in relation to each experiment. For now, it is sufficient to indicate that in almost all essential characteristics our data from V1 in awake, behaving monkeys can be accommodated by the kind of model advanced by Ohzawa, DeAngelis, and Freeman (1990) for explaining data recorded from the anesthetized cat visual cortex. The fact that this kind of model is suitable has strong implications for the way in which V1 neurons respond in the awake animal. First, perhaps surprisingly, there is relatively little evidence of “top-down” influences on the stereoscopic responses of V1 neurons. Sec-

ond, the way in which V1 neurons fail to match the psychophysical characteristics of stereopsis not only indicates the need for further processing beyond V1 but also illustrates the limited scope of the Ohzawa, DeAngelis, and Freeman model as a physiologically based explanation of the perceptual properties of binocular stereopsis.

ANTICORRELATED STEREOGRAMS The first case that we present makes use of anticorrelated random-dot stereograms (aRDS). These patterns do not lead to a coherent percept of stereoscopic depth, but they evoke responses in V1 neurons that are strongly related to the disparity of the stimulus pattern. In a conventional (correlated) random-dot stereogram (cRDS), each bright dot in one eye's image is paired with a bright dot in the other eye's image. Binocular depth is introduced by altering the horizontal position of dots in the images (Julesz, 1971). If the stereogram is constructed on a midgray background, dark dots may also be used, and again the pairing of dots between the eyes is matched for brightness (compare the left-hand and central parts of figure 18.1A). In an aRDS, each bright dot in one eye's image is placed in a horizontal position that would pair it with a dark dot in the other eye's image. The effect of this manipulation on the psychophysical appearance is dramatic and can be observed by attempting to fuse the central and right-hand portions of figure 18.1B. At a sufficiently high dot density, stereopsis is impossible: Although observers continue to be able to discriminate anticorrelated patterns from binocularly uncorrelated dots, it is impossible to discriminate different disparities in anticorrelated patterns (Cogan, Lomakin, and Rossi, 1993; Cumming, Shapiro, and Parker, 1998).

The spatial filtering model for binocular neurons has a characteristic behavior when stimulated with aRDS (see Cumming and Parker, 1997). The model predicts an inversion of the disparity tuning function measured with cRDS. This arises from the way in which bright and dark dots differentially stimulate the ON and OFF zones making up the receptive field of the neuron. With cRDS, the neuron is maximally excited when a bright feature falls within an ON region of the receptive field in *both* right and left eyes (or similarly a dark feature falls within an OFF region). At the equivalent disparity with aRDS, all zones of the receptive field are receiving a bright feature through one eye and a dark feature of the same geometry through the other eye. These effects cancel, leading to a weak response, possibly below the background firing rate.

The most effective responses with aRDS are created when a bright dot stimulates an ON region in one eye's receptive field and a dark dot stimulates an OFF region

A

B

FIGURE 18.1 (A) Sample random-dot stereogram with both correlated and anticorrelated forms (cRDS and aRDS). The left random-dot field and the center field are correlated (so that each dot in one field has a partner of the corresponding contrast in the other field). Binocular fusion of left and center field reveals a foreground region segregated in depth from a surrounding region. The right random-dot field is equivalent to the left field except that the contrast polarity of all dots is inverted. When the right and center field are fused binocularly,

there is no segregation of the foreground and surround regions, and no depth is seen. (B) Example tuning curves of two V1 neurons measured with cRDS and aRDS. The ordinate shows firing rate in impulses per second, and the abscissa shows binocular disparity. Firing rates for cRDS are shown with filled symbols and fitted with a solid line; firing rates for aRDS are shown with open symbols and fitted with a dotted line. The tuning curves with cRDS and aRDS are inverted with respect to each other.

in the other eye's receptive field. As the position of a bright dot in one eye's stimulus is linked geometrically to a dark dot in the other eye, the optimal binocular stimulation requires an offset between the positions of the bright and dark dots. The most favorable size of the offset is equal to the separation of the zones of the receptive field. Hence, the binocular filtering model predicts that when a disparity tuning curve is measured

with aRDS, the peak of the curve should shift to a new disparity, whose value is predictable based on the spatial separation of ON and OFF zones making up the receptive field. Although this argument has been developed as if the cortical neuron had a simple receptive field, the argument also holds for complex cell behavior, because their responses are compatible with a non-linear combination of several subunits with properties

like those of simple cells (Ohzawa, DeAngelis, and Freeman, 1990).

Broadly, V1 receptive fields conform to the expectations of this model: Their disparity tuning functions are inverted by anticorrelation (Cumming and Parker, 1997; figure 18.1). By contrast, we confirmed that, like human observers, the monkeys from whom the V1 neurons were recorded cannot make depth discrimination judgments with anticorrelated stimuli. The combination of these results demonstrates that it is possible to arrange stimuli that generate a large signal within the disparity-selective cells of V1 but nonetheless fail to provide any perception of depth. Even though the amplitudes of the responses to aRDS and cRDS may differ, it is clear that the mere activation of disparity-selective V1 neurons is insufficient for stereoscopic depth perception: The pattern of neuronal responses must be organized in an appropriate way, so as to stimulate neurons that are presumably at a different cortical site, where binocular correspondence is sorted out. It follows that the processing at this other presumed cortical site must be more sophisticated than a simple weighted pooling of the responses from V1, because the population profile of V1 responses by itself can neither predict the difference in appearance of aRDS and cRDS nor account for binocular correspondence.

WINDOWED GRATING PATCHES The previous subsection demonstrated that binocular stimuli that do not lead to stereopsis evoke systematic responses from V1 neurons as the disparity is changed. Here we discuss binocular stimuli that are in principle capable of supporting stereopsis but are actually excluded from the current stereoscopic percept, owing to the geometric arrangement of the stimulus. We used a stimulus that provides for multiple local matches between features on the left and right retinas. The stimulus is a sinusoidal grating pattern delimited by a sharp circular window (see figure 18.2A).

As a preliminary, recall that a grating pattern *without* a window is inherently ambiguous as a binocular stimulus because of the periodic nature of the grating. In our stimulus, the binocular disparity is altered by shifting *both* grating and window horizontally in one eye's image with respect to the other. Consider a receptive field of limited spatial extent that is sensitive only to the local features falling directly within the receptive field. It follows that such a receptive field is not affected by the window so that, as far as the receptive field is concerned, the windowed sinusoid is effectively the same as a grating without a window. There is in reality no basis for determining an unambiguous value for the disparity of the bars of the grating, unless the binocular matching process can be influenced by the disparity of the window.

Figure 18.2A shows that, as the disparity approaches a multiple of the spatial period of the sine wave, then there is also a valid local match for several of the bars at zero disparity. The global disparity is unambiguously signaled by the window and the bars of the grating. But the illustrated manipulation reveals that, if only the bars of the grating are considered, there is a multiplicity of local matches that could stimulate the binocular receptive fields of cortical neurons.

This possibility has been appreciated for some time from a psychophysical and computational perspective (Julesz, 1971; Marr and Poggio, 1976; Mitchison, 1988), where it has been termed the correspondence problem. Psychophysically, the outcome is clear: Human observers respond only to the globally specified disparity in this configuration. (Note that there is no question of a discrepancy between the disparity of the window and the grating. The same globally correct disparity is always signaled by both the window and the bars, but the bars also signal a variety of other locally valid matches.) One way of investigating the signal provided by V1 neurons is to assess whether these neurons respond exclusively to globally correct matches or alternatively to any valid local match within their receptive field.

An example of this test applied to a V1 receptive field is shown in figure 18.3. The response of the neuron with patches of sinusoidal grating shows a peak at the optimal disparity measured with dynamic RDS patterns (as expected), but there is also an additional peak at the repeat period of the grating. Such additional peaks represent strong responses to the local disparities within the pattern. We have tested more than 60 V1 neurons, which all respond similarly to the example illustrated. By contrast, both monkeys have been tested psychophysically and respond in the same way as human observers: The perceptual responses are controlled only by the global disparity of the pattern.

SUMS OF SINUSOIDS There is a potential objection to the previous experiment: It requires some inward propagation of constraints from outside the classical receptive field so that information about the global disparity can influence the processing of local disparities within the receptive field. This process may be impossible within V1, but a more local process could still be at work. Therefore, we have investigated the same question in experiments where the signal that could disambiguate local matches is within the receptive field itself.

In this case, a sum of two spatial sinusoids was used to stimulate the cortical receptive field. The sum of sinusoids results in a spatial pattern of light that has bright and dark features that match up binocularly across the spatial extent of the pattern (see figure 18.2B). This pattern has a

FIGURE 18.2 (A) Stereoscopic figure of a binocular sinusoidal grating pattern with a sharp circular window, as used for testing V1 receptive fields. The stimuli are presented on a mid-gray screen with a dark fixation cross (which the monkey is trained to fixate), and the location of the receptive field is shown schematically by the gray outline box. The shift in position of the window between the left and right eyes defines a binocular disparity, and upon binocular fusion the stimulus appears as a sinusoidal grating occupying a depth plane distinct from the fixation plane. However the local luminance distribution within the receptive field is also consistent with a zero disparity because the disparity of the window is equal to

one spatial period of sine wave. (B) Stereoscopic figures of the binocular sum of sinusoids stimulus. The format is similar to A, but sinusoids at two different spatial frequencies are summed together. The overall pattern has a repeat period governed by the difference between the two spatial frequencies, so if the component frequencies are 3 and 4 cycles per degree the pattern will have repeat period of 1 cycle per degree. Psychophysical testing with these stimuli indicates that the stereo depth judgments of observers are influenced by the repeat period. Neurophysiological results from V1 with these two stimulus types are shown in figures 18.3 and 18.4.

repeat period fixed by the *difference* in the spatial frequency of the two component sine waves. If the neurons in V1 were able to combine information from the two different spatial frequencies within the stimulus, their disparity responses should be dominated by the disparity of the repeat period. The psychophysical responses of both

humans and monkeys are sensitive to an interaction between the sinusoids because the pattern of depth judgments is firmly linked to the globally correct pattern of binocular matches. Thus, psychophysically, the repeat period is effective in constraining stereoscopic depth perception (Thomas, Cumming, and Parker, 1998).

FIGURE 18.3 Data from single cortical neuron recorded in V1 first with dynamic RDS patterns (filled symbols, dashed curve) and then with windowed sinusoidal gratings (open symbols, solid curve). The neuron is clearly tuned for dynamic RDS patterns, but by itself this test does not establish that the neuron responds only to globally correct binocular matches. The data with the windowed sinusoid show two peaks: one at the same position as the peak with dynamic RDS and one at the disparity corresponding to the repeat period of the sinusoid (see figure 18.2A). The stimulus that creates this second peak is perceived by human observers as *nearer* than the fixation plane, whereas the optimal RDS stimulus is *more distant* than the fixation plane.

On the other hand, if the neurons are responsive to purely local information, the simplest prediction is that the neuron's disparity tuning for the sum of sinusoids should be a weighted sum of its responses to each component presented separately (Ohzawa and Freeman, 1986). Qualitatively, the neuron will show peaks in the tuning curve for disparities between noncorresponding features on the stimulus profile.

This pattern of behavior can be seen in the example presented in figure 18.4. The two curves in figure 18.4B show the responses to each sinusoidal component presented separately. Figure 18.4A shows the responses of the same neuron to the two sinusoids presented together, and the curve fitted to this data is a weighted sum of the two sinusoidal curves (from figure 18.4B) that were found to be a satisfactory description of the response to each component presented alone. This result indicates that the neuron responds to each component independently and, as far as disparity tuning is con-

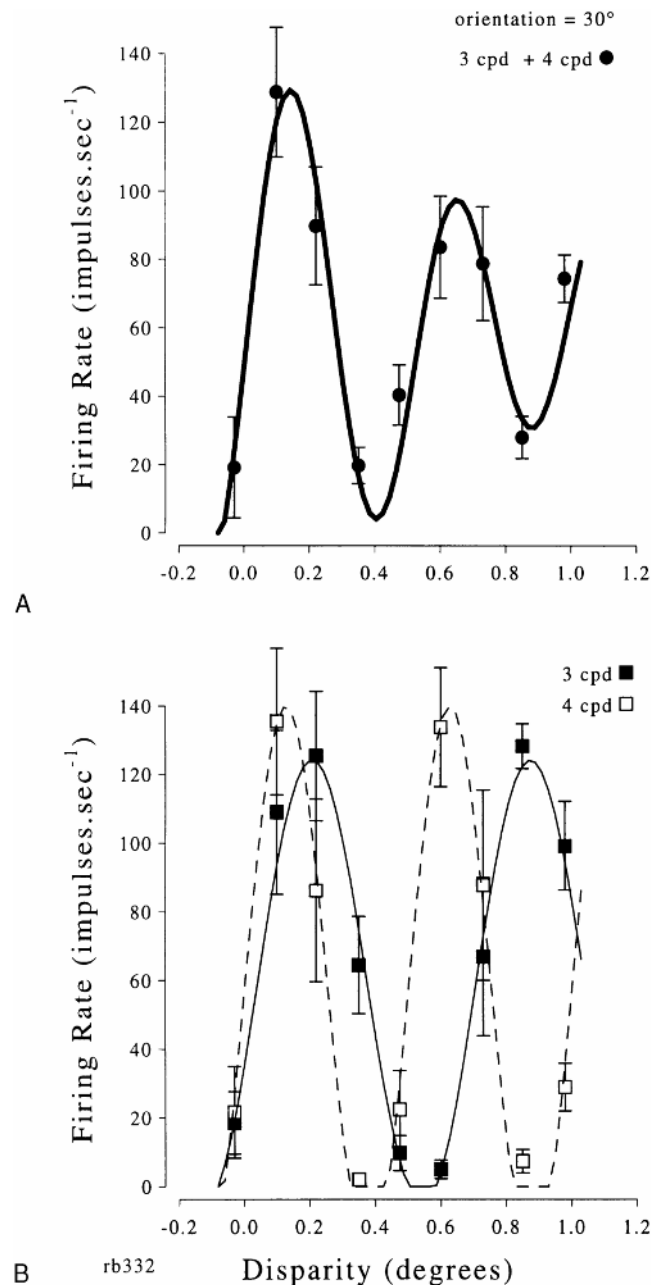

FIGURE 18.4 (A) Data for a single cortical neuron recorded in V1 with the sum of sinusoids stimulus (see figure 18.2B). The peak tuning at about 0.2 degrees of disparity is accompanied by a smaller peak at 0.6–0.7 degrees disparity. The entire tuning curve can be satisfactorily described with a fitted curve defined by a sum of sine waves whose periodicities are fixed by the spatial frequencies of the component sine wave grating patterns. (B) Data from the same cortical neuron as A, showing its response to each component of sinusoid. The responses shown here were collected on trials randomly interleaved with those in A.

cerned, there is no interaction between the sinusoids. This example, like the previous ones, highlights the way in which the disparity-specific responses of V1 neurons are inadequate for explaining the perceptual properties of stereoscopic vision.

RELATIVE VERSUS ABSOLUTE DISPARITY A striking point that emerges from comparing the psychological and the neurophysiological literature on binocular disparity is that each field typically maintains different conceptions of disparity. The point is illustrated in figure 18.5. Neurophysiologists have considered disparity to be the fact that objects at depths other than the fixation plane will project to anatomically noncorresponding points on the left and right retinas (Joshua and Bishop, 1970). Here we will refer to this as *absolute disparity*. Psychologists on the other hand have often considered disparity to be the difference in the projections of two visible features. We will refer to this definition as *relative disparity*.

There are two important respects in which these definitions lead to different properties. First, straightforwardly, at least two visible features are required to define a relative disparity. Second, when the eyes change in convergence in a static 3-D scene, the absolute disparity of features on the retina changes, whereas the relative disparity between features is essentially invariant. Looked at from this point of view, there would be considerable advantage to the binocular visual system in creating a representation of binocular depth based on relative disparity. Such a representation would be stable under changes of fixation in a way that a representation based purely on absolute disparity could never achieve.

It is thus perhaps no surprise that there is considerable psychophysical evidence that the representation effectively used by human observers for binocular depth

judgments is related much more closely to relative disparity than to absolute disparity. The perceived depth of stereoscopic features is typically governed much more by their disparity relative to that of neighboring visual features than by their absolute disparity relative to the binocular point of regard (Westheimer, 1979; Mitchison and Westheimer, 1984; Kumar and Glaser, 1992; Erkelens and Collewijn, 1985; Howard and Rogers, 1995; Glennerster and McKee, in preparation). The problem in assessing the neurophysiological literature on this question is that almost all studies have introduced binocular disparity into the visual stimulus in such a way that absolute and relative disparities have been changed together consistently.

One way to separate the effects of relative and absolute disparity would be to add a surround to a binocular depth target and then manipulate the depth of the surround. This approach allows the relative disparity between the target and its surround to be altered independently. It is straightforward to arrange, but a negative result would be hard to interpret. (We present an example of using this approach in V2 later.) The reason is that, in order to carry out the experiment with an awake behaving primate, the experimenter needs to provide a binocular fixation target. Since we cannot predict in advance how relative disparity is computed, it could be the case that neurons compute relative disparity between the binocular fixation target and the stimulus presented within the receptive field.

FIGURE 18.5 Diagram to illustrate definitions of absolute and relative disparity. The essence of absolute disparity is that it is calculated in a true retinal coordinate frame between *one* visible feature and the binocular location that the eyes are currently fixating. By contrast, the essence of relative disparity is that it is calculated between *two* visible features. Thus, in the left-hand figure, the eyes are looking at the binocular fixation

point f , and a binocular feature d is present at a different depth. The disparity (both absolute and relative) of d with respect to f is given by $\alpha + \beta$. In the right-hand figure, the eyes are rotated to a new fixation position. The absolute disparity of d has decreased (smaller angles between the binocular lines of sight), but the relative disparity between d and the old fixation point f remains the same.

Recently we have investigated this question with the use of a feedback strategy to add a controlled amount of extra absolute disparity to a visual target that also contains relative disparity information. This procedure allows us to manipulate absolute disparity independently of relative disparity. The strategy involves adding an extra absolute disparity to all the visible features within the animal's binocular field including the fixation marker. This situation was achieved by altering the angle between the mirrors that formed the stereoscope through which the animal viewed the targets. This alteration is equivalent to stepping the entire binocular field forward or back by an extra absolute disparity equal to the change in angle between the mirrors. The natural reaction of the animal under this manipulation is to alter vergence to reacquire binocular fixation. It is at this point that feedback is exploited. The animal's binocular eye position is monitored with implanted scleral search coils. As the animal alters its eye position, the measured change in vergence is used to alter the positions of the mirrors so as to maintain the required additional absolute disparity.

This use of feedback is a classic device for investigating the function of the disparity-driven vergence system (Rashbass and Westheimer, 1961). It is important to stress that for our purposes the induced vergence movement is essentially an irrelevant side effect. The important aspect is that we have introduced a known amount of extra absolute disparity. This manipulation has a clear prediction in regard to the properties of cortical neurons that are selective for binocular disparity. If the neuron is computing disparity in a coordinate frame defined by absolute disparity, then a consequence of the addition of an extra absolute disparity is that the preferred disparity of the neuronal tuning function should shift by an amount equivalent to the added absolute disparity. If the neuron is computing disparity in a coordinate frame defined by relative disparity, then the extra absolute disparity should have no effect.

Representative results for a V1 neuron are shown in figure 18.6. This neuron shows changes in its preferred disparity when additional absolute disparities are included in the display. Hence the neuron computes disparity as absolute disparity rather than relative disparity. All 54 neurons that we have explored in V1 show this pattern of behavior.

SUMMARY OF V1 RESULTS We have explored several features of the disparity-related responses of V1 neurons. In all cases, the responses of these neurons are incompatible with predictions based on the hypothesis that these neurons are directly involved in controlling the perceptual process. It appears that V1 represents a

preliminary stage in the generation of the stereoscopic process. By analogy with earlier studies of motion processing (Movshon et al., 1985), disparity processing appears to proceed with V1 performing a binocular spatiotemporal filtering of the retinal outputs, which is then followed by the elaboration of higher-order properties in extrastriate cortical areas.

Binocular responses in extrastriate cortex

Some of the earliest studies on the extrastriate cortex indicated the presence of disparity-selective neurons in these visual areas (Hubel and Wiesel, 1970; Maunsell and Van Essen, 1983). By itself this observation is unremarkable. There is a sense in which any binocular neuron may be expected to show some measurable disparity tuning if it has spatially restricted receptive fields in the left and right eyes. When the centers of the receptive fields are determined in the left and right eyes and projection lines are drawn out from those centers, the lines will cross at some point in binocular space (assuming there is no vertical misalignment of the receptive fields). This geometric organization is sufficient to enable the neurophysiologist to measure some disparity tuning from a neuron with this receptive field structure. This fact illustrates quite nicely the general point that no firm conclusions about the role of neurons in perception can be deduced simply from the fact that they are tuned to some particular sensory parameter.

Thus we concentrate on recently acquired evidence that neurons in the extrastriate cortex are indeed more closely involved in controlling the animal's stereoscopic percept than neurons in V1. Cortical area V2 has long been implicated in the processing of binocular information, and we point to some features of disparity processing in V2 that appear qualitatively different from observations in V1. Other evidence from extrastriate cortex comes from cortical area V5(MT), which until now has been chiefly associated with the perceptual processing of motion information.

RESPONSES TO RELATIVE DISPARITY IN V2 We employed the technique of directly probing responses to relative disparity by manipulating the disparity of a surround region while the disparity of a central region covering the receptive field was held constant. This changes dramatically the perceptual appearance of the depth configuration in the dynamic random-dot figure. A neuron that is sensitive to depth relationships should have its disparity-tuning function shifted to different preferred disparity (or otherwise modulated) by this change in configuration.

Figure 18.7 shows the disparity tuning curve of a V2 neuron measured under two conditions. In the first case, the surround region is maintained at a disparity of -0.4° relative to the binocular fixation point (i.e., always more distant); in the second case, the surround is maintained at disparity of $+0.4^\circ$ (in front of the fixation point). In both cases, the disparity tuning is measured by changing the disparity of the center to the values shown on the abscissa. The main (upper) figure shows the responses of the neuron as a function of disparity; the inset (lower) figure shows the animal's vergence state at each disparity.

The main upper figure shows that the neuron's tuning curve is shifted along the abscissa by the change of background configuration in the direction expected for a neuron that is sensitive to relative disparity. However, the size of the shift is too small for this neuron to be considered as purely sensitive to relative disparity: There is some residual sensitivity to absolute disparity.

Another cautionary feature of the results is shown in the lower figure, where there is clear evidence of a change in vergence that is linked to the change in background configuration (see the section "Feedback effects in V1?"). It appears that this change in vergence is too small to account for all of the change in the neuron's tuning curve but undoubtedly contributes to it. The change of vergence is somewhat unexpected, given that the animal has a clear binocular fixation point and that the surround region is limited in size and does not traverse the binocular fixation point. Evidently, measurements of binocular eye position are essential in evaluating claims about sensitivity to relative disparity, since if the animal were always to converge at the same distance as the *surround region* in this experiment, one could falsely conclude that the neuron is sensitive to relative disparity.

In our limited sample so far, only a few neurons in V2 behave like that in figure 18.7 by showing evidence for

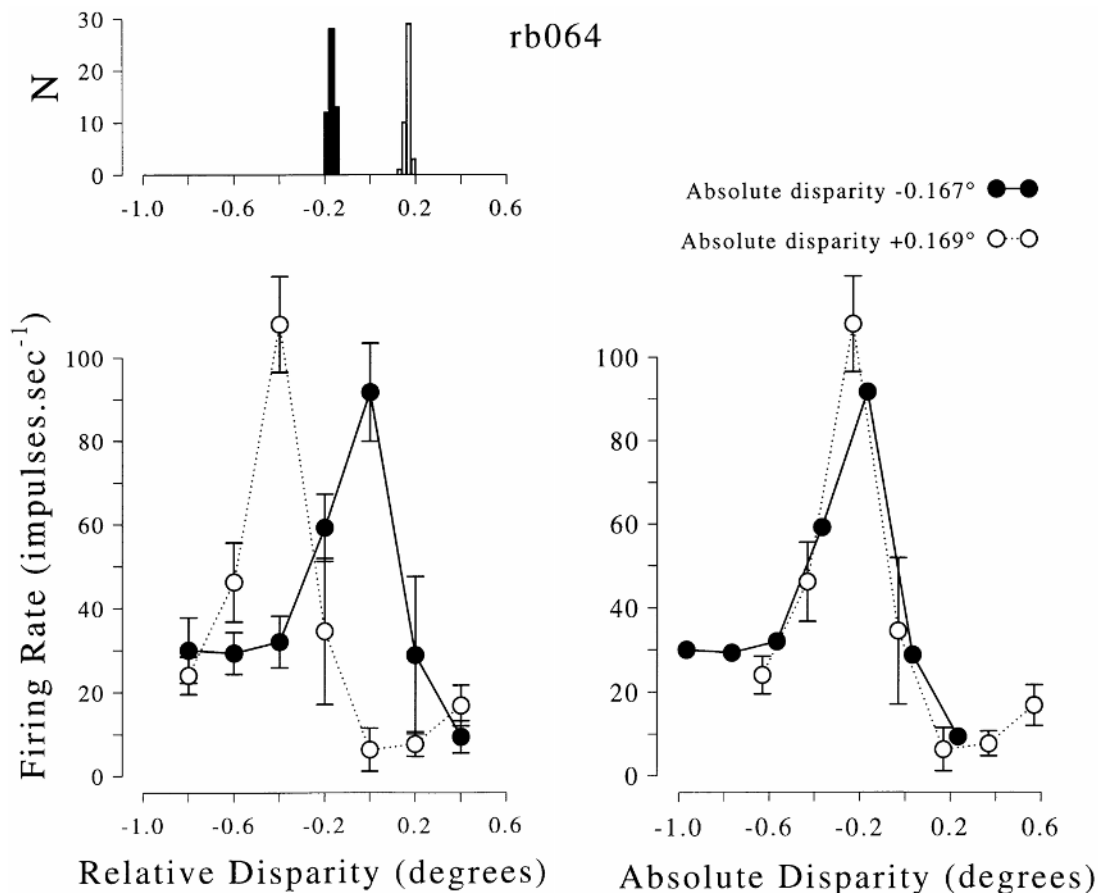

FIGURE 18.6 Responses of a V1 cortical neuron to manipulation of absolute and relative disparity with dynamic random-dot stereogram stimuli. The lower left graph shows the firing rate of the neuron (impulses per second) as a function of relative disparity (degrees) under two different conditions of added absolute disparity. The values of the added absolute disparity were controlled by feedback from the mea-

sured vergence position (see text) and are plotted in the upper left graph. The lower right graph shows the same neuronal tuning data replotted with an abscissa with a scale of absolute disparity. The tuning curves from the two conditions now coincide, thus demonstrating that this V1 neuron responds to the absolute not the relative disparity of stereoscopic stimuli.

sensitivity to relative disparity as well as absolute disparity. The majority of neurons in V2 show no sensitivity to the background configuration in this procedure, and we conjecture that they are primarily responsive to absolute disparity. Given existing evidence for the clustering of different types of neuron in V2 (Peterhans and von der Heydt, 1993; Roe and T'so, 1995), it will be interesting to see whether evidence for clustering of neurons with sensitivity to relative disparity emerges as more data are collected.

RESPONSES OF NEURONS IN V5(MT) TO PERCEPTUALLY AMBIGUOUS STIMULI For this study we employed perceptually ambiguous stimuli: figures that permit two or more distinct perceptual interpretations by the observer. A classic example from perceptual psychology is the Necker cube (figure 18.8). In these experiments, we used a motion stimulus that reverses in depth similarly to the Necker cube. The motion figure consists of a set of dots depicted on a transparent cylindrical surface that is rotating about its axis. Human observers may perceive this cylinder as rotating either clockwise or counterclockwise. The perceived direction of rotation of the cylinder is linked to the relative depth assigned to the moving dots forming the figure. A vertically oriented cylinder will rotate clockwise (as viewed from above) if the leftward moving dots in the pattern are assigned to the nearer surface and the rightward moving dots to the further surface. If the cylinder reverses direction of rotation, the depth relationships necessarily change.

If an observer views a figure of this type with one eye and the display is produced by orthographic projection, there is no information that the observer can use to determine the "true" direction of rotation. If, however, binocular viewing is used, then stereo disparities can be used to indicate to the perceptual system which of the two surfaces is in front of the other. In this case, the direction of rotation becomes unambiguous. We exploited binocular vision to train monkeys to indicate the direction of rotation of cylindrical motion stimuli. The fact that this stimulus is unambiguous allows us to create the appropriate reward contingencies for training the monkey. The training can be taken further by decreasing the size of the stereo disparities down to the neighborhood of stereo threshold.

It is then possible to include occasions on which the animal is presented with a cylinder in which the front and rear surfaces have the same disparity. Such trials are essentially impossible to distinguish from near-threshold examples, which actually include some disparity and thus have a demonstrably correct answer. The responses on the ambiguous trials indicate an unbiased measure of the

FIGURE 18.7 Responses of a cortical neuron recorded in V2 to dynamic random-dot stereograms, where the foreground (central) region was at the absolute disparities indicated on the abscissa and the background (surround) region was placed at either $+0.4^\circ$ or -0.4° relative to the fixation target. The lower inset graph shows the average state of the monkey's convergence on the fixation target (0.0°) upon the same trials during which the neuron was recorded. The change of background disparity induces a shift in the tuning of the cortical neuron, which is in the correct direction for a response that is exclusive to *relative* disparity but is smaller than the 0.8° shift expected on this basis. Nonetheless the shift in the neuronal tuning is too small to be accounted for by the small shifts in convergence state.

subject's perception of the cylinder with motion cues alone.

The neuronal responses to these rotating cylinder targets (Bradley, Qian, and Andersen, 1995; Dodd et al., 1997; Bradley, Chang, and Andersen, 1998) confirm that many neurons in V5(MT) carry disparity-related signals, as well as their well-known direction selectivity. The response varies systematically as the disparity between the front and back surfaces of the cylinder is altered. Preliminary testing of the receptive field with single planes of dots was used to assess the receptive field location and size, direction selectivity, and disparity preference of the neurons. The cylinder was then placed so that its size and location matched the receptive field and at least one of its surfaces fell within the direction and disparity preference of the neuron. In general, the neuron changed its response monotonically as the disparity of the surfaces within the cylinder changed, so that the output of the neuron could potentially contribute to the animal's judgment about the perceived configuration of the cylindrical target.

FIGURE 18.8 The upper figure shows a well-known example of a perceptually reversible figure, the Necker cube, for which the alternative 3-D interpretations are indicated diagrammatically at the right of the figure. The lower figure shows the principle behind the perceptually reversible rotating cylinder used in our experiments. The cylinder is depicted with dots placed at random locations on its surface. The moving dots are represented here by arrows that point in the direction of their motion and whose length shows their speed. The motion flow field on the left is inherently ambiguous and can support either of the two interpretations shown on the right. The addition of binocular stereo cues separates the front and rear surfaces of the transparent cylinder and thereby fixes the direction of rotation.

The interesting case is the response of the neuron on trials where all the dots forming the cylinder have zero disparity. The external stimulus is constant, but the animal's report about the configuration differs from trial to trial. Using exactly this approach, Bradley, Chang, and Andersen (1998) have already shown that some MT neurons have enhanced responses when the animal makes a behavioral choice consistent with the properties of the recorded neuron.

We wanted to find out whether the single-trial responses of the neurons were *predictive* of the animal's response, and if so with what statistical reliability. We examined two probability distributions of the neuron's responses: one for trials on which the animal reported that the stimulus was rotating counterclockwise and one for trials on which the report was clockwise (see figure 18.9). This experiment revealed that the neuronal firing

pattern was in general predictive of the animal's responses. More precisely, the response of some neurons yielded a highly reliable index of the animal's choice. In some cases, there was almost no overlap between the two probability distributions. We employed the analyses of choice probability described by Britten and colleagues (1996) and discovered that choice probabilities could be as high as 0.93 with an average value of 0.68. These values are much higher than those found by Britten and colleagues (1996) for neurons in the same cortical area during the performance of a direction discrimination task with moving patterns of dots.

Clearly, this result reflects a strong correlation between the neuronal responses and the animal's perception, but its cause remains to be determined. Recently, DeAngelis, Cumming, and Newsome (1998) have taken matters one step further by employing electrical stimulation while the animal is performing a stereo depth judgment task. They succeeded in shifting the monkey's perceptual decisions such that stimulation in a region of V5(MT) preferring "near" disparities resulted in a greater proportion of "near" responses from the animal (see DeAngelis et al., chapter 21 of this volume). These various results suggest that V5(MT) may have an important role in some aspects of stereoscopic vision.

Feedback effects in V1?

Cortical area V1 receives a large number of afferent connections from extrastriate cortex as well as connections from the visual thalamus. Recently it has been argued that these connections provide a feedback system that creates a modulation of the responses of V1 neurons, in a way that depends upon the perceptual context of the stimulus (Lamme, 1995), including its binocular disparity (Zipser, Lamme, and Schiller, 1996). The experiments presented here are relevant to this discussion. Feedback signals from higher cortical areas are one way in which V1 neurons could disambiguate stereoscopic matches (in the case of the windowed sinusoids) or develop a sensitivity for relative rather than absolute disparity. The fact that no such effects can be observed in V1 argues that contextual modulation of V1 responses does little that is useful for stereoscopic processing. So the first point is that, for the case of stereo vision, contextual modulation fails to achieve what would be a useful perceptual function. In this respect, its functional role remains mysterious.

Nonetheless, contextual modulation adds a complexity to the simple picture of V1 that we advanced earlier. We may identify three possible routes by which the responses of V1 neurons could be modulated. The first is by intracortical connections from within V1, which are

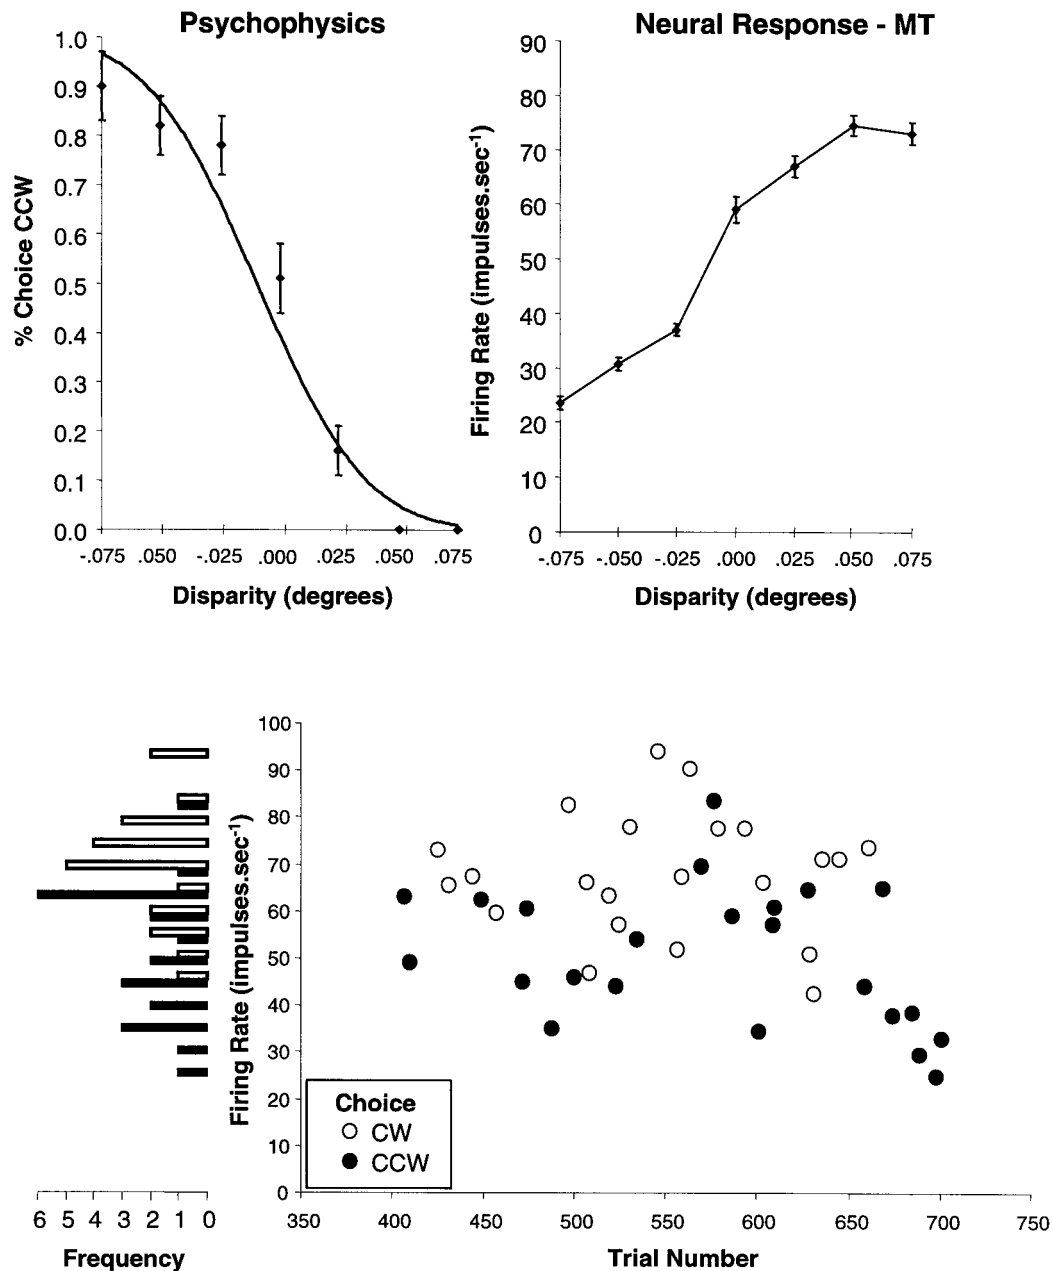

FIGURE 18.9 Simultaneously acquired neurophysiological responses from a single cortical neuron recorded in V5(MT) and psychophysical responses from the same animal to the rotating cylinder stimulus described in figure 18.8 as a function of the binocular disparity between the two surfaces of the cylinder. The upper pair of graphs shows that both the psychophysical and the neural responses change systematically with binocular disparity. The lower graph extracts the responses on trials where the binocular disparity was 0.0° and the cylinder was in-

herently ambiguous. The firing rates are plotted against trial number with the animal's choices of clockwise (CW, $N = 22$) and counterclockwise (CCW, $N = 23$) shown separately. These data are summarized at the left as two frequency distributions of firing rate, one for each type of choice made by the animal. The separation of these two distributions can be summarized by the choice probability (here 0.823), which indicates the tightness of the correlation between the firing of this individual neuron and the perceptual choices made by the animal.

often assumed to be the route by which influences outside the classical receptive field can alter the stimulus specificity and responsivity of the neuron, even when the animal is anesthetized and the eye position is held fixed by paralyzing agents (e.g., Levitt and Lund, 1997).

The second route is by feedback from connections from other locations in the brain, generally assumed to be largely from other extrastriate cortical areas (Lamme, 1995; Zipser, Lamme, and Schiller, 1996; Lamme and Spekreijse, chapter 19 of this volume). The third route is

more indirect, via a stimulus-induced change in eye position, which is clearly a potential problem in the awake, behaving animal.

We emphasize two points here. First, when a static random-dot field is presented to the V1 receptive field of an awake, behaving monkey (as in Zipser, Lamme, and Schiller, 1996), there is typically a burst of firing closely following stimulus presentation, and then the firing rate settles down to a much lower rate, which is readily elevated again by the visual consequences of a small eye movement. A great deal of the firing in the later phases of the stimulus duration therefore depends not particularly on the stimulus parameters but on the pattern of eye movements made by the animal. Second, we demonstrated earlier that binocular neurons in V1 are selective for absolute rather than relative disparity, so any shift in vergence position will affect the signals in V1 neurons. Clearly, it is essential to monitor the positions of both eyes. Even when a visual neuron is insensitive to binocular disparity or monocularly driven, a change of vergence can alter the position of the visual stimulus with respect to the receptive field.

Zipser, Lamme, and Schiller (1996) argue that the disparity relationships between a foreground area covering the receptive field and a background area outside the classical receptive field create contextual modulation of V1 responses. This proposal is potentially at variance with our view that V1 neurons do not respond to relative disparity. We have therefore sought to reproduce as closely as possible the conditions under which the responses of V1 cortical cells appear to be modulated by the manipulation of disparities outside the classical receptive field. Although we can observe phenomena similar to those described, in a substantial number of cases we can establish that small shifts in vergence are responsible for the effect. Zipser, Lamme, and Schiller measured the position of only one eye during their experiments, and it is relevant to note that the design of their experiment requires the animal to maintain convergence while an extended field of random dots is introduced at a nonzero disparity.

Such conditions are ideal for evoking a transient change in vergence (as seen in figure 18.10 and studied extensively by Busetini, Miles, and Krauzlis, 1996). In the absence of records of binocular eye position, it is impossible to evaluate the extent to which the data from the Zipser, Lamme, and Schiller study are contaminated with vergence eye-movement artifacts. The data shown in figure 18.10 demonstrate a transient change in vergence induced by the background. The animal's vergence is initially at zero degrees of disparity, moves away from zero degrees when the background is introduced at a nonzero disparity, and then moves back to

zero degrees as the animal reacquires convergence on the fixation target itself. As shown in figure 18.10, the experiment examines the case where the occurrence of the vergence transient is separated in time from the presentation of a perceptually segregated stimulus over the receptive field. If a background of nonzero disparity is presented 700 ms *prior* to the stimulus on the receptive

rb589.0

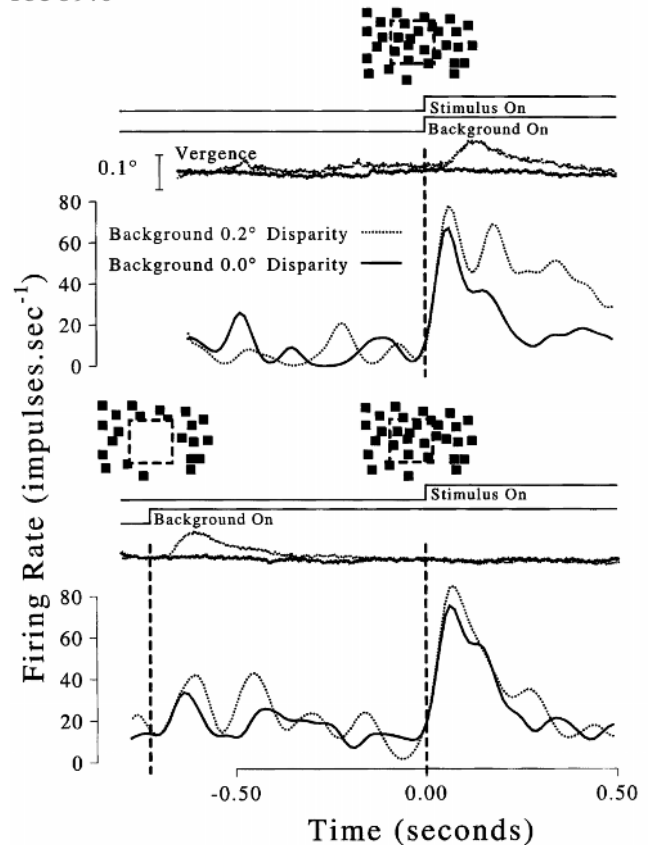

FIGURE 18.10 Responses of V1 neuron to static random-dot stereograms in the manner of Zipser, Lamme, and Schiller (1996). The stereogram consists of a central stimulus that is always at 0° disparity and covers an area about twice the “classical receptive field,” and an extensive background region that may be either at 0.2° or at 0.0° disparity and covers a wide area including the animal's binocular fixation point. The figures plot smoothed measures of the instantaneous firing rate in a single neuron and measures of convergent eye position averaged over 8–10 trials. Simultaneous presentation of the receptive field stimulus with background at nonzero disparity causes an enhanced firing from the neuron with a more extended time course (upper graph). This enhancement may be attributable to the small induced vergence movement rather than the perceptual segregation of the stimulus from the background. The lower graph presents the same experiment except that the background is presented 700 ms before the receptive field stimulus. The small induced vergence movement occurs in response to the background presentation, and the stimulus-driven responses of the neuron are now identical regardless of the background disparity.

field, the transient wobble in vergence is complete before the stimulus arrives on the receptive field. This manipulation eliminates the apparent effect of background disparity on the responses to the stimulus in the receptive field.

None of this discussion affects the general question of the existence of modulatory influences from outside the classical receptive field in V1. Such effects have of course been demonstrated in the anesthetized, paralyzed preparation (e.g., Levitt and Lund, 1997), where systematic eye movements are not a problem, and we have confirmed their existence in our own recordings. However, these modulatory influences do not support what would be an important functional role in providing V1 neurons with sensitivity to relative disparity. From the present evidence, we are uncertain whether binocular disparity actually contributes to any contextual modulation effects in V1. What is certain is that a substantial fraction of the disparity-induced modulations previously reported in V1 are most likely attributable to the effect of eye movements.

Conclusions

This study has developed and applied a sequence of challenging tests of binocular processing to the striate cortical (V1) representation of the visual scene. The outcome of all these tests points to the need for additional processing beyond V1 to account for many psychophysical characteristics of binocular stereopsis. Both V2 and V5(MT) are extrastriate cortical areas that may be involved in the elaboration of stereoscopically related signals. V2 appears heterogeneous but may well yield interesting information with more extensive sampling. Recent results from V5(MT) are very striking: Tight correlations between neural activity in V5 and the psychophysically effective signals for binocular depth have been demonstrated here, and clear effects of electrical microstimulation on binocular depth judgments have been found (DeAngelis, Cumming, and Newsome, 1998; see DeAngelis et al., chapter 21 of this volume).

On the other hand, there is relatively little neurophysiological data concerning the processing of fine-grain stereo information in V5(MT), and one lesion study in V5(MT) has reported no loss of performance in a stereoscopic depth task (Schiller, 1993). In view of the fact that at least some single neurons in V1 have sensitivities for stereoscopic depth approaching that of the psychophysical observer (Pointon, Cumming, and Parker, 1998), an educated guess would be that signals serving fine-grain stereopsis are sent to extrastriate sites other than V5(MT). In this regard, the much larger number of neurons in V2 and V4 compared with V5(MT) suggests that

some compartments of V2 or V4 may contain highly relevant signals.

19 Contextual Modulation in Primary Visual Cortex and Scene Perception

VICTOR A. F. LAMME AND HENK SPEKREIJSE

ABSTRACT Through the receptive field properties of neurons in the cortical visual areas we mainly observe the feedforward cascade of information processing, transforming visual input into specific outputs. Horizontal and feedback connections are expressed by contextual modulation of neuronal activity. In area V1, where receptive field properties reflect only low-level processing, contextual modulation can be observed that represents fully evaluated perceptual saliency of the features within the receptive field. It is proposed that contextual modulation reflects a process distinct from receptive field-based processing. This process integrates information from distant areas in visual cortex, neurophysiologically “highlighting” those neurons that represent image elements or features of objects that stand out perceptually. It may thus serve as a binding tag, and be a neurophysiological correlate of object-based attention or visual awareness.

Receptive fields and the functions of visual areas

The receptive field of a neuron in visual cortex is classically defined as the part of the visual field from which action potential responses can be elicited by presenting a stimulus. This stimulus has to meet a number of requirements for a cell to respond, and the receptive field is “tuned” to particular features. A well known example is that cells in primary visual cortex (V1) respond better to some orientations of luminance contrast than to others (Hubel and Wiesel, 1968, 1977). Traditionally, the function of a visual area is derived from the set of features to which the receptive fields in the area are tuned. We call area MT a “motion” area because many of its neurons are tuned to direction, speed, or other aspects of motion (Maunsell and Van Essen, 1983; Allman, Miezin, and McGuiness, 1985a; Newsome, Mikami, and Wurtz, 1986; Movshon et al., 1986; Maunsell and Newsome, 1987); we call V4 a “color” or a “form” area because cells are tuned to certain wavelengths (Zeki, 1973, 1980) or elementary shapes (Desimone and Schein, 1987; Gallant et al., 1996); and so on. This view is further substan-

tiated by the fact that lesions of these areas often cause deficits that are more or less specific to the processing function we attribute to that area by means of its receptive field tuning properties (Dean, 1979; Newsome et al., 1985; Heywood and Cowey, 1987; Maunsell and Newsome, 1987; Wild et al., 1985; Schiller and Lee, 1991; Schiller, 1993). Thus we arrive at a modular organization of visual processing (DeYoe and Van Essen, 1988; Livingstone and Hubel, 1988) that is still disputed in its strictness, but nevertheless has profoundly pervaded our thinking on the roles of cortical areas in vision.

Spatially limited receptive field analysis performed within separate modules requires extensive and dynamic interactions to combine the distributed information. Anatomical connections provide a framework for those interactions (Felleman and Van Essen, 1991). Within each module, horizontal interactions integrate information from separate parts of the visual field (Gilbert and Wiesel, 1989; Gilbert, 1992). Between modules, information is transferred in a feedforward fashion from low-level modules to higher-level ones. But in addition, feedback connections transfer information in the reverse direction (Salin and Bullier, 1995). When going upstream through the hierarchy of visual areas, receptive fields obtain tuning properties of increasing complexity and incorporate information from increasing parts of the visual field (Maunsell and Newsome, 1987). Receptive field properties therefore seem to reflect mostly the convergent-divergent feedforward cascade of information processing. Feedback connections are highly diverging, but their influence on cells in lower areas is not reflected by the small receptive field sizes in an area such as V1 (Salin and Bullier, 1995). The longest of the horizontal connections within V1 spread over distances much larger than the size of receptive fields would suggest (Gilbert, 1992, 1993). We must conclude that a view based solely on receptive field properties and modular processing does not take into account the interactions mediated by a set of connections that numerically outweigh the set of feedforward connections.

Not long after the discovery of cortical receptive fields and their tuning properties, it was recognized that once

VICTOR A. F. LAMME The Netherlands Ophthalmic Research Institute, Amsterdam, The Netherlands
HENK SPEKREIJSE Graduate School of Neurosciences, AMC, University of Amsterdam, Amsterdam, The Netherlands

the receptive field contains some stimulus, the response to this stimulus may be modulated by surrounding stimuli (Jones, 1970). A surprising and key feature of this phenomenon is that the modulating stimuli do not evoke a response when presented alone, and hence are outside the classical receptive field. The early experiments, in area 17 of anesthetized cats, typically used bars or gratings as receptive field and surround stimuli. It was found that modulatory effects can be evoked from large distances, but are strongest at short distances. Both facilitation and inhibition have been reported; these could be either nonspecific or any combination of orientation and direction of motion-specific (Blakemore and Tobin, 1972; Maffei and Fiorentini, 1976; Nelson and Frost, 1978; Allman, Miezin, and McGuiness, 1985b). Also in areas beyond V1, modulation from outside the receptive field has been reported (Desimone et al., 1993; Allman, Miezin, and McGuiness, 1985a, b). The phenomenon thus seems to be a general property of visual processing by cortical cells.

Where does that leave the concept of receptive field-based modular processing? The coding capability of a neuron will merely be weakened when its firing rate can equally well be modulated by a change in receptive field stimulus and by a change in its context. What would be the function of these modulations? Recent findings on the properties of contextual modulation suggest a role entirely distinct from the encoding of receptive field-based information. Its characteristics bear no specific relation to the receptive field tuning properties (Lamme, 1995). Contextual modulation reflects, better than the receptive field properties, the process of combining the information from the many neurons that respond to particular features or parts of an image. This could imply a role for contextual modulation in feature binding, attention or even visual awareness. Within that context, the properties of contextual modulation in primary visual cortex will here be compared with properties of perceptual organization.

V1 is an interesting area in this respect. Its receptive field tuning properties are well characterized. Receptive fields are very small, so global analysis, reflecting perceptual interpretation of the scene as a whole, is least expected here on the basis of receptive field-like processes. On the other hand, V1 is at the top of the hierarchy in terms of feedback connections. Activity representing the convergence of information from all visual areas would be expected to clearly reflect a fully evolved perceptual interpretation. In V1, therefore, we should expect receptive field processing of a sort most detached from scene perception but contextual modulation closely related to it. There is ample evidence for the former; we will now take a look at evidence for the latter.

Phenomenology of contextual modulation in V1

CONTEXTS MODULATING PERCEPTION OF SINGLE IMAGE ELEMENTS A single line segment on a blank background is a visual scene only rarely encountered. In natural scenes, line segments or contrast edges are embedded in many others, forming edges, textures, and object boundaries, the one occluded by the other. The perceptual interpretation of a single line segment strongly depends on its context. Line segments form ideal stimuli for V1 cells. V1 receptive fields are often tuned for their orientation, direction of motion, disparity, size, contrast, or color (Hubel and Wiesel, 1977; Schiller, Finlay, and Volman, 1976; DeValois, Albrecht, and Thorell, 1982; Livingstone and Hubel, 1988; Poggio, 1995). V1 neurons are therefore classically viewed as encoding information about line segments or contrast edges within their receptive fields. But what happens to the neuron's response when the perceptual context of a line segment within the receptive field is manipulated?

Compared to a single line segment (figure 19.1a), multiple line segments (figure 19.1b) have to share perceptual saliency among one another. The single line segment strongly draws attention to itself. The set of line segments, rather, draws attention as a group, such that each individual line segment is of much less importance. In V1, we find a correlate of this in contextual modulation. If we imagine the line segment of figure 19.1a to fall on a V1 receptive field, and the surrounding line segments added in figure 19.1b to fall outside, we see that responses of neurons are generally stronger in the first situation than in the second (Knierim and Van Essen, 1992).

The reduced saliency of the center line segment can be alleviated by having its orientation differ from those of the surrounding elements, creating a perceptual "pop-out" of the center element (Nothdurft, 1991, 1994). This (partial) restoration of perceptual saliency finds a parallel in that the responses of many cells in V1 are larger in figure 19.1c than in figure 19.1b, although not as large as the response would be for a lone element (figure 19.1a) (Knierim and Van Essen, 1992). That this is not a local, mechanistic phenomenon is illustrated by figure 19.1d. Here, too, the center line segment is surrounded by line segments of different orientations. There is no perceptual pop-out, though, because the orientation difference between center and surround does not differ from orientation differences among elements in general (see also Nothdurft, 1985, 1994; Landy and Bergen, 1991). Likewise, responses are not different from the responses to the figure 19.1b stimulus (Knierim and Van Essen, 1992; Kapadia et al., 1995).

FIGURE 19.1 The context of a line segment changes its perceptual saliency. (a) A lone line segment is perceptually most salient. (b) The same line segment, now embedded in similar ones, draws much less attention as an individual. (c) The line segment may pop out when its orientation differs from that of the surrounding line segments, restoring its perceptual saliency to some extent. (d) Global stimulus aspects are taken into consideration, since a similar local orientation difference does not produce pop-out when surrounding elements all have different orientations. (e) Perceptual grouping by coaxial alignment may cause line segments to segregate, increasing their perceptual saliency. When a V1 neuron is stimulated by presenting these displays, so that its receptive field (dotted circle) covers only the same center line segment in all cases, contextual modulation of its responses signals the perceptual saliency of the center line segment.

When line segments group into elongated chains, they again segregate from a background of randomly oriented line segments (figure 19.1e). Whether such grouping occurs depends on the relative alignment of the line seg-

ments. Coaxial line segments group better than parallel ones. In general, grouping depends on relative distance, angle, and axial offset (Field, Hayes, and Hess, 1993; Kapadia et al., 1995; Kovacs, 1996). It was found that these same factors influence contextual modulation in V1 neurons. Line segments that are flanked by collinear ones (Nelson and Frost, 1985) or, more generally, by line segments that lower detection thresholds, elicit larger responses (Kapadia et al., 1995). It was not fully clear from this study how these enhancements compare to the more general finding of inhibition by surround stimuli (e.g., figure 19.1b). A recent study (Polat et al., 1998) showed that at low contrasts, collinear stimuli result in enhancement, while at high contrast they result in inhibition.

IMAGE ELEMENTS BELONGING TO SURFACES It is just a small step from the stimuli of figure 19.1e to the stimulus of figure 19.2a. The more or less one-dimensional chain of lines has now been extended to two dimensions. As in figure 19.1c, the grouped line segments, which now group on the basis of similar orientation, segregate from a background of line segments of another orientation. An important feature is added though—the notion of boundary and surface. Where line segments join line segments of the orthogonal orientation, we observe the boundary between the square figure and the background. Line segments within the boundary comprise the surface of the figure.

We have analyzed how contextual modulation modifies responses depending on whether the receptive field contains line segments belonging either to the boundary or surface of the figure or to the background. This can be done by using complementary stimulus pairs, leaving receptive field stimulation identical in all cases (Lamme, 1995; see also figure 19.5a)—a prerequisite for studying contextual modulation separately from receptive field processing as such. Figure 19.2b shows population responses from neurons in V1 of the awake monkey for the three different receptive field contexts: background, boundary, or surface. The response to line segments within the receptive field that belong to the background consists of a transient followed by a slow decay. When the same neurons respond to identical line segments that now comprise the boundary between figure and ground, the same initial transient is observed; but from a latency of about 80 ms on, the response is higher than the response to background elements. We observe the same phenomenon when the receptive field is at the center of the figure, although the latency at which figure and background responses start to diverge is now about 100 ms. In figure 19.2c, these data, combined with data from several other positions of the receptive field relative to figure and ground, are represented in a 3D format. On the front

a

b

c

horizontal axis, the different positions of receptive field relative to figure and ground are represented. The contextual modulation observed in figure 19.2b can now be ob-

FIGURE 19.2 The neural correlate of figure-ground segregation in V1. (a) Line segments of similar orientation perceptually group together and segregate from line segments of another orientation. The center square is considered a textured figure on a textured background, which perceptually seems to continue behind it. The boundary between figure and ground belongs to the figure surface. (b) Responses in V1 to the figure-ground display are larger when the receptive field (open circle; RF) of a neuron is on the boundary or on the surface of the figure than when it is on the background. (While receptive field stimulation is left identical in these three cases, see Lamme, 1995.) Note that contextual modulation (gray shading) only develops after 80–100 ms after stimulus onset; the initial transient is identical in all three cases, showing that only what happens within the receptive field determines the responses up to 80 ms. (c) Responses in V1 with the receptive field at 15 different positions relative to figure and ground, such that the contextual modulation is “scanned” across a line passing over and through the figure. The 15 positions are on the *x*-axis (in front), time is on the *y*-axis (side), and response strength is on the vertical axis. Responses are identical up to about 80 ms after stimulus onset (note the horizontal wave at the back of the plot, which is at 50 ms). Then, responses are “highlighted” at the boundary between figure and ground first. This is followed by an equal response enhancement for all positions of the receptive field within the figure, compared to responses for positions of the receptive field on the background.

served for all positions of the receptive field within the boundaries between figure and ground. Initially, at 80 ms, contextual modulation only highlights the boundaries between figure and ground. But from about 100 ms on, all elements within the figure show contextual modulation relative to the background, as if a neural image of the figure is stamped out of the neural image of the background, closely reflecting our figure-ground percept.

These data illustrate an important point, one that is not self-evident from the results discussed in the previous section: Contextual modulation takes into account local grouping and segregation criteria, but it can also ignore them, taking into account the figure-ground polarity of the segregating elements as well. At the center of the figure, the elements are surrounded by similar ones; nevertheless, contextual modulation is the same as at the edge, where elements are flanked by orthogonal ones. Immediately outside the boundary between figure and ground, elements are similarly flanked by orthogonal ones, but contextual modulation is absent (that is, responses are identical to background positions farther away). Instead of reflecting local discontinuities, or differences between receptive field center and surround stimuli, contextual modulation in these experiments reflects the figure-ground relationships of the surfaces in the scene. Again, the neurons representing the perceptually most salient elements of the scene, in this case the

whole figure, are highlighted relative to neurons representing less important elements.

This kind of figure–ground contextual modulation bears no relation to the receptive field properties of the neurons recorded from Lamme (1995). For example, the effects described above can be recorded in cells without any sharp orientation tuning. Also, it is found that the effects can be elicited by figure–ground displays defined by a variety of cues. On the population response level, contextual modulation is of the same magnitude for figures defined by differences in orientation, direction of motion, disparity, color, or luminance (Lamme, 1995; Zipser, Lamme, and Schiller, 1996). When all these cues are combined, modulation is not additive, but identical to the one-cue situation. This shows again that the modulation signals figure–ground relationships instead of feature-specific differences: A figure is a figure, no matter how it is defined.

Interesting observations were also made using more complex displays than the one of figure 19.2a. For example, when rivalrous patterns are presented to the two eyes, so that segregating squares are visible in either eye alone, contextual modulation is present only when the cyclopean percept (i.e., the combination of the images of the two eyes; see Kolb and Braun, 1995) is that of a figure segregating from ground. This implies that contextual modulation reflects perceptual interpretation of—instead of information present in—the retinal images. Also, when a textured frame is shown on a textured background, the square region within the frame is perceived as continuous with the background surrounding the frame. It has been shown that, in that case, modulation for the center square is absent, as if signaling the perceptual interpretation that this “square” is a continuation of the background (Zipser, Lamme, and Schiller, 1996). Under specific conditions, a stronger modulation right at the geometric center of the figures in figure–ground scenes can sometimes be observed (Lee et al., 1998). It has been proposed that this plays a role in representing the medial axes of objects (Kovacs, 1996; Lee et al., 1998).

Similar modulations of neuronal activity in V1 can be observed in relation to perceived brightness of surfaces. The perceived brightness of a surface can be modulated by the brightness of surrounding surfaces (figure 19.3a). It was found that V1 neurons modulate their activity according to changes in perceived brightness when these changes are induced by luminance modulations of surrounding surfaces that do not impinge on their receptive fields (Rossi, Rittenhouse, and Paradiso, 1996). Perceived brightness can also be changed by presenting a surface, followed by the presentation of a surrounding surface of equal luminance. This is called metacontrast masking (figure 19.3b). Depending on the time interval between the presentation of the first surface and the second sur-

FIGURE 19.3 Changing apparent brightness of a surface. (a) The apparent brightness of a gray square depends on the luminance of the surrounding square. Both the center gray squares are printed at the exact same gray level, but appear brightest when surrounded by a black frame. This is called simultaneous contrast. (b) When a luminance square is followed by the presentation of a frame of equal luminance, the apparent brightness of the preceding square is reduced, depending on the onset asynchrony between first and second stimulus. This is called metacontrast masking. In both cases, it has been observed that V1 neurons modulate their responses according to the reduced saliency of the center square when this is positioned over their RF.

rounding surface, the perceived brightness of the first surface is diminished (Schiller and Smith, 1968). Under ideal conditions perception of the appearance of the first surface may totally vanish. It was reported that the responses of V1 cells, whose receptive fields were centered on the center disk of a metacontrast stimulus, were modulated according to the reduced apparent brightness of that center disk. This modulation was not present in an early part of the response, only in a later one (Bridgeman, 1980).

LATENCY OF CONTEXTUAL MODULATION EFFECTS AND THE ROLE OF FEEDBACK Responses in area V1 have a minimal response onset latency of about 30 ms (Maunsell and Gibson, 1992; Nowak et al., 1995). This can be viewed as the time at which processing in V1 sets off. With respect to the question as to what type of connections, (feedforward, horizontal, or feedback) may mediate contextual modulation, it is important to know how long it takes for these modulations to occur once activity has started in V1. The suppressive effect that arises from presenting a stimulus in the immediate surround of a receptive field stimulus (figure 19.1b) takes a very short time to develop. Results of no latency difference (Müller, Krauskopf, and Lennie, 1997) and a latency difference of just 7 ms (Knierim and Van Essen, 1992) have been reported. Orientation-specific effects

[i.e., comparing the effect of an identical background with that of an orthogonal background producing perceptual pop-out (figure 19.1b vs. figure 19.1c)] take about 20 ms (Knierim and Van Essen, 1992). Modulation related to figure-ground segregation of surfaces (figure 19.2a) may start from 30 ms up to about 70 ms after response onset, depending on the cue that segregates figure from ground (Lamme, 1995; Zipser, Lamme, and Schiller, 1996) and on the distance of the receptive field from the edge of the surface (figure 19.2c). For metacontrast masking (figure 19.3b), no effects were found prior to 110 ms (Bridgeman, 1980); and assuming a minimal V1 response latency of 30 ms for these data, one may conclude that contextual modulation related to apparent brightness takes about 80 ms to develop.

Once processing has started in V1, contextual modulation thus takes a wide range of times to express itself. The latency of the effects seems to depend on the complexity of the computations underlying the modulation and the spatial extent of the part of the scene that is taken into consideration. Short latency contextual modulation effects are more likely to be generated by feed-forward and horizontal connections than by feedback connections since the latter would presumably take some time to exert their effect. However, for some extrastriate visual areas, minimal response latencies as short as those for V1 have been reported (Nowak et al., 1995; Nowak and Bullier, 1997), so even short latency effects may be caused by feedback. Indeed, it has been shown that more short-range contextual effects, like those described in relation to figure 19.1, depend on feedback from V2 (Bullier et al., 1996; see also Lamme, Supér, and Spekreijse, 1998, for a review).

More complex or spatially long-range effects that take considerable time to develop are very likely to depend at least in part on feedback. To study this dependency directly, one has to inactivate extrastriate areas while recording from V1. In figure 19.4a, we show the results of recording figure-ground related modulation in an animal that had sustained a large lesion to the extrastriate areas, ipsilateral to the recording site. Contextual modulation is still evoked at the boundary between figure and ground, but is no longer present for the surface elements of the figure. Figure-ground related modulation thus depends on the integrity of the extrastriate areas (Lamme, Zipser, and Spekreijse, 1997).

The role of contextual modulation in visual processing

CONTEXTUAL MODULATION REFLECTS A GENERALIZED NOTION OF PERCEPTUAL SALIENCY In the above results, contextual modulation is shown to reflect three

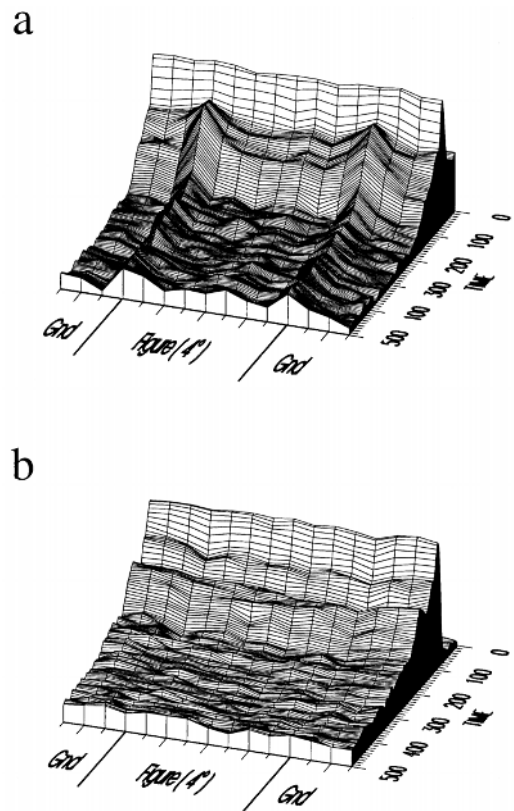

FIGURE 19.4 The effects of extrastriate lesions and of anesthesia on figure-ground related contextual modulation. Similar “scans” of contextual modulation across a line passing over and through the figure of figure 19.2a are shown as in figure 19.2c. In (a), the results are shown from recordings from an animal that had sustained a lesion to the peristriate belt of visual cortex. This lesion more or less isolates V1 from feedback from extrastriate areas, with the exception of area V2. Note that contextual modulation is only present for positions of the receptive field overlying the figure-ground boundary, and that responses are the same for background positions and positions inside the square. In (b), the results are shown from recordings in intact animals, but anesthetized with isoflurane. Here, normal receptive field responses are recorded but contextual modulation is absent altogether.

different aspects of image elements: segregation or pop-out, detectability, and apparent brightness. An element is said to pop out when its detection is independent of the number of surrounding elements. For example, in figure 19.1c, the time it takes to recognize that one element differs from the rest would be equal for this amount of distractors and for a far larger amount. In other words, it does not take serial or attentive scrutiny of the individual elements of the scene to recognize that one is different from the rest. Surfaces may also pop out, as in figure 19.2a; this phenomenon is called texture segregation.

Detectability of image elements refers to a different psychophysical measure. By presenting an element at various low contrasts, its detection threshold (for in-

stance, 50% detection chance) can be determined. In this way, it was found that detection threshold lowers, i.e., detectability increases, when line segments are flanked by collinear ones (figure 19.1e) (Polat and Sagi, 1994; Kapadia et al., 1995; Kovacs, 1996). It was also found that detectability is higher within an enclosed area of the scene than outside (Kovacs and Julesz, 1994), which is reminiscent of the contextual modulation effects for surfaces (Lamme, 1995; Lee et al., 1998). Apparent brightness is typically determined by comparing the brightness of one test surface with that of another. In a two-alternative forced-choice procedure, subjects are asked to tell which of two surfaces appears brighter (figure 19.3; Bridgeman, 1980).

These three measures have some essential differences. For example, one analyzes performance at detection thresholds, whereas the other two may be used at more normal levels of contrast. Also, whether pop-out elements always have lower detection thresholds or increased apparent brightness is an open question. They do share common ground, however, which may be best described as a generalized notion of perceptual saliency. In this context the term is defined as a measure of how well an image element is capable of drawing attention to itself. Elements that pop out, or have lower detection thresholds, or are brighter than others all share a common property—they attract attention. This intuitive relation between the three measures is underscored by the findings of contextual modulation. When context produces pop-out, increases detectability, or increases apparent brightness, contextual modulation always results in an *increase* in the neuronal responses. When single-unit responses are analyzed, cells might, in some cases, exhibit opposite effects (Allman, Miezin, and McGuiness, 1985a; Lamme, 1995; Zipser, Lamme, and Schiller, 1996; Kapadia et al., 1995; Polat et al., 1998). At the multiunit or population level, however, the outcome is always very clear; response amplitude reflects the proposed generalized notion of perceptual saliency. This can be seen as an argument in favor of the thesis that perception takes into account population effects rather than responses of individual neurons.

It is probably also crucial to record these effects in awake animals. The contextual modulation effects described here have been recorded in awake and perceiving animals. But even in anesthetized subjects receptive field surround effects are present (see Allman, Miezin, and McGuiness, 1985b; Sillito et al., 1996; Kastner, Nothdurft, and Pigarev, 1997). The extent to which these are similar to contextual modulation in the awake animal is not fully clear. Thus far, only one investigation has directly compared the awake and anesthetized con-

dition in the same animals and with the same stimuli. Here, it was found that, at the population response level, figure-ground related contextual modulation is present only in the awake and perceiving animal (figure 19.4b; Lamme, Zipser, and Spekreijse, 1998). In the anesthetized monkey, contextual modulation recorded from single units is often both positively and negatively correlated with perceptual saliency; and it might be that on the population level these effects cancel. This could imply that subprocesses underlying normal contextual modulation are still operational under anesthesia, but fail to produce a coherent effect at the population response level.

CONTEXTUAL MODULATION AS A BINDING TAG Modular processing introduces a problem. The computations performed within the separate modules have to be combined to produce a coherent output. The role of vision is to segregate objects from background and from each other, and to select particular ones for behavioral responses. Image elements and features, processed by cells at different locations, have to be combined so that we are able to manipulate the objects we encounter (the “binding” problem; Singer and Gray, 1995; Treisman, 1996). To some extent this might be explained by the feedforward cascade of increasingly complex receptive field tuning properties observed when going upstream through the hierarchy of visual areas (Barlow, 1995; Maunsell and Newsome, 1987). But strict feedforward processing introduces many problems, particularly in terms of the number of neurons needed to account for every possible combination of inputs and outputs (the “combinatorial explosion”). In this context, many have advocated population coding as opposed to “grandmother” cell hypotheses (Abeles, 1982; Georgopoulos, 1991; Singer and Gray, 1995). In population coding, cells might at some time be engaged in a processing task with one set of neurons (an assembly), but at another time with a different set. Here, the problem is how cells are recognized or “labeled” as belonging to the same assembly. For example, in processing an image such as figure 19.2a, a label should separate the neurons that code for the elements of the figure from the neurons that code for the background.

It has been proposed that synchrony of firing between cells might act as such a label (Singer and Gray, 1995). It has been found that neurons in V1 fire their action potentials in relative synchrony when their receptive fields (RFs) are stimulated with a coherently moving bar. This synchrony is reduced when the neurons are co-stimulated with separate bars (Gray et al., 1989; Freiwald, Kreiter, and Singer, 1995). On the basis of these results, neurons whose RFs fall within the figure region of an image should fire in synchrony with neurons whose RFs

fall within the figure, and not fire in synchrony with neurons whose RFs fall on the background. We studied synchrony for neuron pairs when both RFs lie within the figure (in-in) and when the RFs lie on either side of the boundary between figure and ground (in-out), as shown in figure 19.5a. Synchrony depended on low-level parameters such as relative distances between RFs, and relative orientation of line segments stimulating the two RFs. In figure 19.5b, we compare synchrony for the same pairs of V1 neurons under in-in conditions (ordinate) and in-out conditions (abscissa). The stimulus was a moving random dot figure-ground display (Lamme, 1995). For these neuron pairs, there is no difference in synchrony between the two conditions. In combination with our other results on this topic (Lamme and Spekreijse, 1998), this indicates that synchrony in V1 does not label cells as belonging to either figure or ground.

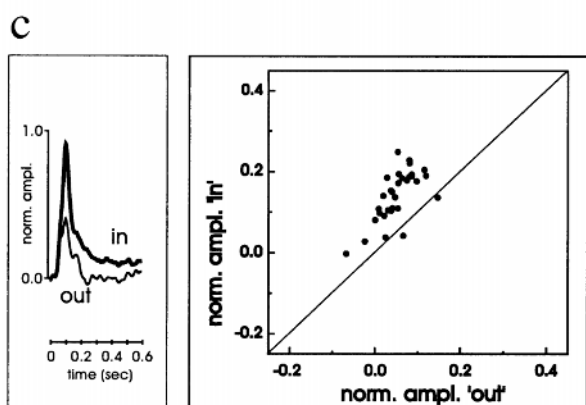

Alternatively, enhanced firing rate could serve as a binding tag. Cells engaged in the processing of features or elements of the same object would have an enhanced firing rate compared to other cells. In figure 19.5c, we compare response amplitudes of the same sites that formed the pairs in figure 19.5b. Almost all neurons had higher responses to elements of the figure than of the background. Also, remember that a particular neuron will typically show an equal amount of response enhancement for all elements of a figure, whether close to the edge or within its center (figure 19.2c; Lamme, 1995). This shows that, indeed, response enhancement may serve as a tag that binds the elements of the figure together. A drawback of firing rate versus synchrony as a binding tag is that with the former it is more difficult to separate several assemblies from each other (Singer and Gray, 1995). It is, however, questionable whether the visual system is capable of representing many objects simultaneously. Experiments on change blindness indicate that not more than two to three objects are represented by the visual system at a time (Irwin, 1997; Rensink, 1997).

CONTEXTUAL MODULATION AND VISUAL ATTENTION AND AWARENESS Perceptually salient elements are strong bottom-up attention grabbers. In that sense, contextual modulation can also be viewed as representing the amount of attention that is *drawn* by elements in the image. Attention is more commonly viewed as being *given*; where many objects may draw attention, only a few can receive it. Attention is often considered a top-down influence on early processing (Rizolatti, Riggio, and Sheliga, 1994). Lesions to extrastriate areas suppress contextual modulation for figure-ground displays (figure 19.4a; Lamme, Zipser, and Spekreijse, 1997), but other types of modulation arise so fast that top-down in-

fluences seem unlikely. Whether contextual modulation reflects attention that is drawn by or given to an object thus awaits further experimentation. The distinction might, however, be nonexistent. Pop-out and segregation were initially considered to be performed preattentively, but now it is becoming clear that these depend on the same attentional resources as serial search tasks. Pop-out and segregation break down when attention is focused on something else (Treisman, 1993; Joseph, Chun, and Nakayama, 1997). In other words, attention that is drawn depends on what is already given. Attention is probably best considered a push-pull between bottom-up and top-down mechanisms.

A further distinction is between spatial and object-based attention (Duncan, 1984; Treisman, 1993, 1996; Vecera and Farah, 1994). In feature integration theory, (Treisman 1993), attentional mechanisms are required to turn features into objects. Features of the same object may be represented in separate maps (e.g., color and orientation), and by focusing attention to the location in space where the two coincide these features can be tagged as belonging to the same object. Parallel search, as in pop-out, or serial search differ only in the size of the spatial attention window (Treisman, 1993; Wolfe and Bennett, 1997). Objects can also overlap in space. Features therefore also need to be tagged as belonging to a particular object. This requires object-based attention (Duncan, 1984; Treisman, 1993; Vecera and Farah, 1994).

Numerous studies have reported modulatory effects of focal spatial attention on neuronal activity in many cortical areas, including V1 (Motter, 1993; for a review, see Desimone and Duncan, 1995). Neural correlates of object-based attention are less well documented, but it has been shown in a PET study that object-based attention has effects on activity in striate cortex (Fink et al., 1997). It is unlikely that contextual modulation is a reflection of focal spatial attention. Two separate and distant textured figures (as in figure 19.2a) on a background evoke the same amount of modulation as one (Lamme, Zipser, and Spekreijse, 1998). On the other hand, figure-ground contextual modulation precisely highlights the elements of an object that segregate from background (figure 19.2), and thus could serve as a correlate of object-based attention. Also, we have recently shown that the responses in V1 to one of two overlapping lines are enhanced when attention is focused on that line by means of a curve tracing task (Roelfsema, Lamme, and Spekreijse, 1998). This object-based attentive enhancement bears strong similarities to the contextual modulations described here, in that they are typically of long latency (~200 ms) and of the same order of magnitude. It might be, therefore, that contextual modulation is a correlate of attention-based feature grouping of elements

into objects. When adopting an attention-based theory of feature binding (Treisman, 1993), this is in fact the same role as suggested in the previous section.

It is a small step from visual object-based attention to visual awareness. Currently, there is a lively debate about the neural correlate of visual awareness (Block, 1996; Storer, 1996). In this discussion, a pivotal role seems to be taken by V1. It has been argued that V1 should be ex-

FIGURE 19.5 Comparing synchrony and amplitude modulation as a binding tag in figure-ground segregation. (a) Responses of, and cross-correlations between, the multiunit activity (MUA) of pairs of electrodes were obtained with figure-ground stimuli at various positions relative to the receptive fields (RFs). The figure could cover both RFs (in-in), or one of the RFs, but not the other (in-out). In this case, the different shades of gray are meant to represent opposite directions of motion of random dots. (b) The left panel shows normalized cross-correlograms between two electrodes implanted in monkey V1, for the two conditions, in-in, and in-out. The right panel shows normalized cross-correlation coefficients for condition in-out (abscissa) against normalized cross-correlation coefficients for condition in-in (ordinate), both at time lag 0, for all pairs of recording sites in two animals. No significant differences are found between these two conditions. (c) In the left panel responses of one electrode to the stimulus where the RF was within the square figure (in = thick line) are superimposed on those where the RF was outside the figure, i.e., on the background (out = thin line). The right panel shows the amplitudes (average of 0–600 ms) of the responses of all electrodes of the two animals. Amplitude of response to the out condition is on the abscissa, to the in condition on the ordinate. The difference between the two conditions is significant at $p < .000001$.

cluded from the neural substrate of visual awareness because activity can be recorded in V1 of which one is not aware (Crick and Koch, 1995; He, Cavanaugh, and Intriligator, 1996). However, some have shown effects of focal attention in V1 (Motter, 1993), and the relation between attention and visual awareness is obvious (Treisman, 1993; Newsome, 1996). In this chapter, we have shown modulations that bear a strong relation to the perceptual interpretation of the scene as a whole. Furthermore, contextual modulation in V1 is selectively suppressed by anesthesia, while RF tuning properties remain unaffected (Lamme, Zipser, and Spekreijse, 1998). Thus, V1 RF tuning properties do not reflect perception, but response amplitudes do. Apparently, some types of V1 activity are more intimately related to perception than others and both types of activity coexist in a single area. In other words, while V1 may host much in the way of perceptually impenetrable signals, this in no way implies that other aspects of its activity should not become accessible to, or even constitute, conscious visual perception. In the end, it will be more fruitful to look for the *processes* that constitute perception than for the *areas* that do so.

Conclusions

Contextual modulation in V1 takes into account information from very distant parts of the visual scene to signal a generalized notion of perceptual saliency of the image elements that fall on the receptive field of the neuron that is recorded. It thus highlights those neurons

in the brain representing features that are, in some way, more important to our behavioral decisions than others. In that sense, it is strongly related to neurophysiological correlates of attention, and possibly of visual awareness. Contextual modulation can be viewed as part of a general class of neurophysiological phenomena that sit on top of the feedforward, receptive field-based, modular processing stream. This class reflects the horizontal and feedback interactions in the brain. Understanding these interactions will be crucial in understanding perceptual organization, attention, and visual awareness.

20 Computational Neuroimaging: Color Representations and Processing

BRIAN A. WANDELL

ABSTRACT Establishing the relationship between neural activity and private experience requires reasoning that links psychological and neural measurements. Because the experimental variables in these two disciplines differ, rigorously linking the data requires a quantitative analysis of the information represented in corresponding psychological and neural measurements. Color appearance is a good psychological domain for working out the link because several quantifiable rules, such as trichromacy, light adaptation, opponent-colors responses, and low spatiotemporal resolution for color, are well characterized. First, these fundamental color appearance properties are described. Then, current hypotheses linking color appearance and neural activity are discussed. Finally, recent experiments using functional magnetic resonance imaging to analyze the relationship are reviewed.

The brain interprets the retinal image as a collection of objects having various perceptual features, including color, motion, and texture. One important goal of vision science is to discover the computational principles and specific neural mechanisms used by the brain to infer the presence of objects and their properties from the retinal image. This chapter reviews the main ideas concerning how color appearance is derived from the signal encoded within the retina.

Illusions remind us that our visual experience is not a measurement of the physical stimulus, but rather a neural computation. Some visual illusions offer significant insight into these neural computations. The illusion in figure 20.1 demonstrates that even a sensation as simple as brightness is an interpretation of the image and not just a measurement of the number of photon absorptions. The square patches on the left side of the figure appear light; the square patches on the right side appear dark. In fact, the squares on the left reflect the same amount of light and cause the same number of photon absorptions as those on the right. The appearances differ because of neural computations.

The illusion suggests that brightness is a perceptual explanation of surface reflectance. The number of photons reflected from an object confounds the reflectance of the object and the ambient illumination level. The

brightness of the squares is better explained as a comparison between the patch and the background. If we assume that the background reflectance is constant across the page, this comparison estimates the reflectance: Were the background constant, the patch on the left would be more reflective than the one on the right. It is a reasonable guess that the neural computations incorrectly treat the large background as uniform and that the difference in photon absorption rates are caused by an illumination gradient. Hence, we experience the two patches as having different brightness even though they send equal numbers of photons to our eyes.

For two reasons, color appearance is a useful model system for exploring the neural basis of visual experience. First, a great deal is known about the biological basis of color encoding in both human and animal vision (Wandell, 1995). Because we understand many of the fundamental rules concerning the encoding of color, we can begin with a firm understanding of how color information enters the visual pathways. Second, when compared to many other visual sensations, color appearance is simple. Color sensations can be well described using only a few primitive terms—such as hue, saturation, and brightness. By studying the neural basis of color appearance, we may be able to deduce some principles about the neural basis of visual awareness.

In this chapter, I will explore some of the current hypotheses of how color appearance is computed within the visual pathways. The first part of this review summarizes the basic principles of color appearance. The second part introduces recent working hypotheses about the neural computations underlying these color appearance principles.

A central conclusion of the chapter is this: Information about the wavelength composition of light must be represented throughout much of visual cortex. Information about the wavelength composition of the retinal image is used by neural circuits engaged in image segmentation, object recognition, motion, and other important visual tasks. In this way, color information is part of the vast array of unconscious visual processing.

BRIAN A. WANDELL Neuroscience Program and Department of Psychology, Stanford University, Stanford, Calif.

FIGURE 20.1 Color appearance is a neural computation. When uniformly illuminated, the pair of squares on the left and right send the same number of photons to the eye. The

pair on the left appears lighter because neural computations of brightness includes information from the surrounding regions, and not just the photon absorptions from the object itself.

To identify the neural circuitry specifically associated with color appearance, we must identify the specific color signals that share the properties of behavioral color appearance judgments. I will suggest some ways functional magnetic resonance imaging can be used to measure cortical signals in human observers and discriminate neural signals that correlate with appearance from those that provide wavelength information for other visual circuits.

Principles of color appearance

Human color appearance judgments are based on three fundamental principles: trichromacy, opponent-color representations, and color constancy. This section contains a brief review of these principles and some discussion of their neural basis.

TRICHROMACY The neural representation of the visual world begins with the responses of four interleaved photoreceptor mosaics: three types of cone photoreceptors and one type of rod photoreceptor. These mosaics simultaneously encode information about pattern, motion, and many other aspects of the visual world. The

rods function primarily under very low light levels, where human observers are monochromats, so that any pair of lights can be matched to one another simply by adjusting their relative intensities. Signals initiated within the cones permit us to discriminate between lights of different spectral composition. Hence, in the remainder we will focus on signals initiated by the cone mosaics.

When other factors such as the spatiotemporal properties of the stimuli and ambient viewing conditions are held equal, two lights that cause the same number of absorptions in the three cone classes appear identical. Because there are only three cone types, people have only a modest ability to discriminate among lights with different *spectral power distributions*. The spectral power distribution (SPD) of a light source measures how much power there is at each wavelength. The SPD is commonly used to specify the wavelength composition of a light. When studying color vision, spectra are ordinarily specified over a range from about 370 to 730 nanometers (nm). Figure 20.2 shows the spectral power distributions of three lights that, despite the obvious differences in their SPDs, cause the same number of cone absorptions. These lights are metameric to one another.

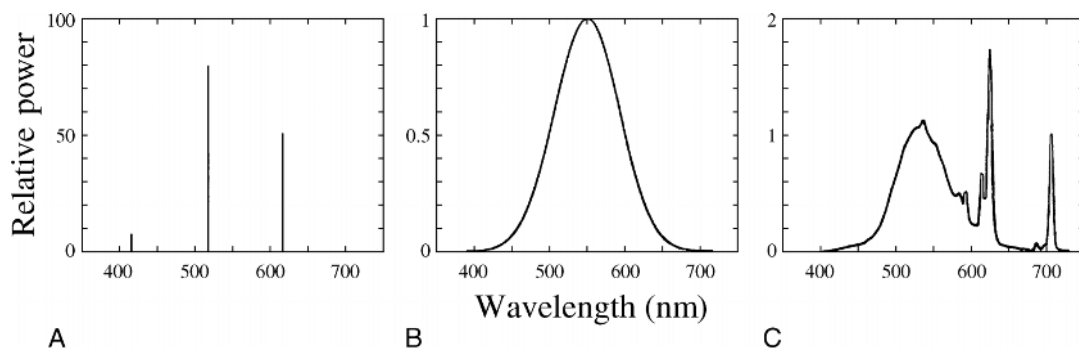

FIGURE 20.2 Three different spectral power distributions that have the same color appearance are shown. (A) The sum of

three monochromatic lights, (B) a Gaussian spectrum, and (C) light emitted from a typical television monitor.

Two lights that cause the same number of absorptions in each cone class, but have different spectral power distributions, are called *metamers*. With only a few caveats, it is possible to arrange a match between any test light and a second light that is the sum of three, fixed, primary lights. The ability to arrange a color match using three primary lights is called *trichromacy* and flows from the presence of three cone types. Because photopigment absorptions follow nearly linear rules over a large range of intensities, it has been possible to develop a complete characterization of the set of metameric lights. The ability to control and create metamers is a key aspect of most color reproduction technologies (Brainard, 1995; Wandell, 1995).

The trichromatic character of color matching is a fundamental principle of color appearance. But there is no immediate connection between color matching and common color-appearance terms, such as hue terms like red and green, or general terms like light and dark. Many factors, including the spatiotemporal structure of the stimulus and the ambient background, strongly influence the perceived color appearance. Thus the retinal encoding by three cone types defines a fundamental limit on the range of color experiences, but there is much more to be understood about color appearance than simple matching.

To see this point, consider that during the color-matching measurements the observer never describes the stimulus appearance, but only establishes a match between a pair of stimuli. The difference between setting a match and judging appearance is implicit in figure 20.1. Suppose that we set a color match between a pair of square targets, such as the upper and lower squares on the left. These two squares cause the same pattern of cone absorptions, so they still match in appearance when they are shifted to the right. While the match between the two squares is preserved, the color appearance of both squares changes. Hence, from the point of view of color matching nothing changes as the position shifts from the left to right. From the point of view of color appearance, there is a significant change.

Thus a theory of color appearance requires more information than a theory of color matching. Matches between two common spatial temporal patterns, seen within a common framework, can be explained by knowing only the light absorptions within the cone outer segments. But, measuring and explaining color appearance requires much more.

OPPONENT COLORS A second key concept in color appearance is our inability to experience certain hue combinations. While logically possible, these hue combinations are beyond the scope of our neural apparatus and

are never offered as a visual explanation of the retinal image. These forbidden color combinations are called *opponent colors*.

To understand this phenomenon, first consider a pair of color sensations that can co-occur, red and yellow. We have no difficulty perceiving these two components within a single color; orange is the common name for such a color. Nor do we have any trouble identifying hues that appear both reddish and bluish at the same time; purple is the common name for such a color. But, observers never identify a hue as being reddish and greenish at the same time. Similarly, people never report seeing a color that is yellow and blue at the same time. A spot may appear yellow *or* blue or neither. But a spot never appears yellow *and* blue. There is no logical or physical reason that there should be such opponent colors. The cause must be how the brain encodes color appearance.

Since Hering's (1905) initial description of opponent colors, there have been many behavioral and theoretical studies of opponent colors. One way to demonstrate the significance of an opponent-colors representation is to ask subjects to name the colors of spectral test lights. The words red and green are essentially never used together, nor are the words blue and yellow. Other combinations, such as red and yellow, occur frequently (Boynton and Gordon, 1965).

A second way to see the effects of the opponent-colors representation is to measure the detection threshold of various colored test lights. The points in figure 20.3 show the L and M cone contrast levels at detection threshold, and the solid curve is an ellipsoid drawn through these points. These data were measured using a spatially blurry spot whose contrast increased and then decreased slowly over time, as shown by the insets.

To understand why these data suggest a powerful opponent-colors signal, consider how much contrast is needed to see an L cone stimulus, an M cone stimulus, and an L plus M cone stimulus. A test light that excites only the L or M cones can be seen at less than 1 percent contrast. But a test light that excites the L and M cones together requires 6 percent contrast in both cones, considerably more. Hence, stimulating the M cones reduces the visibility of an L cone signal. This opposition of the signals suggests an L-M opponent-colors neural representation. Other sensitivity measurements also suggest a blue-yellow opponency (e.g., Pugh, 1976; Pugh and Mollon, 1979; Mollon, 1982).

Behavioral experiments suggest that color information is represented in an opponent-colors format comprising three neural pathways. One pathway encodes the red-green dimension of color. An increase, say, of activity in this pathway corresponds to a red percept, while a

FIGURE 20.3 Detection threshold contour for colored stimuli. The horizontal and vertical axes measure L and M cone contrast levels. Threshold measurements are shown by the open points. When the stimulus modulates only the L cones (horizontal axis) or only the M cones (vertical axis), threshold is much lower than when the stimulus modulates both the L and the M cones (upper right direction). The lowest cone contrast levels occur when the L and M cones are modulated with opposing sign (upper left direction). The solid curve shows an interpolated ellipsoidal curve. The insets in the upper left show spatial and temporal representations of the test stimulus. (Source: Wandell, 1985.)

decrease of neural activity corresponds to a green percept. A second opponent-colors pathway represents blue-yellow, and a third neural pathway represents light-dark. This neural format explains opponent-colors appearance: If different sensations are coded by increments (red) and decrements (green) within a single set of neurons, then red and green cannot be experienced at the same location and time. Similarly, blue and yellow are a forbidden combination.

To study one of the three neural pathways, it is necessary to silence the other two. To do so, it is essential to identify the set of stimuli that *fail* to excite each pathway. Then, by finding a signal that fails to excite, say, the red-green and the light-dark pathways, we can isolate the blue-yellow pathway. A stimulus that appears neither red nor green is said to be in red-green equilibrium. Such a stimulus might appear blue, yellow, or achromatic.

The collection of red-green equilibrium stimuli can be characterized using simple geometric figures. To see how, first consider figure 20.4A (see color plate 7). This drawing shows a method of representing colored stimuli as three-dimensional points. In the representation used

in this figure, the stimuli are described in terms of the red, green, and blue phosphors' intensities, relative to the background. Second, consider a surface that passes through the points representing red-green equilibrium stimuli; figure 20.4B (see color plate 7) shows four different views of such a surface. This red-green equilibrium surface divides those stimuli that appear reddish (concave side) from those that appear greenish. The surface is shaded to suggest the bluish and yellowish appearance of the equilibrium stimuli. Because the equilibrium stimuli appear neither red nor green, they should be invisible to neurons coding red-green color appearance. Hence, the shape of this surface can be used to identify the properties of neurons that might carry the opponent-colors appearance signal for red-green. (Burns et al., 1984; Chichilnisky and Wandell, 1995; Ejima and Takahashi, 1985; Mausfeld and Niederee, 1993).

Spatial resolution Based on the opponent-colors measurements already discussed and others, it is possible to present observers with simple patterns that stimulate one of the three color pathways and fail to stimulate the other two. By isolating such mechanisms, it is possible to study their spatial and temporal properties. Studies of the spatial sensitivity of the red-green and blue-yellow pathways demonstrate that opponent-colors pathways have very poor spatial resolution compared to the light-dark pathway. Consequently, fine spatial patterns higher than roughly 30 cycles per degree (cpd) invariably *appear* to be a light-dark variation around the mean no matter what their true physical composition. Red-green spatial variation does not exceed roughly 20 cpd (correcting for the optics) or 10 cpd (through natural optics). Blue-yellow spatial variations extend only to 5 or 6 cpd. Figure 20.5 summarizes measurements of spatial sensitivity of the red-green opponent-colors pathways from three different laboratories.

At high spatial frequencies, observers have reduced contrast sensitivity to the red-green patterns compared to light-dark patterns. At low spatial frequencies, observers are relatively more sensitive to red-green targets. The same spatial frequency dependence holds for the blue-yellow opponent-color dimension. The poor spatial responsivity of the eye to color is a very large effect. Consequently, it is used widely to create efficient image representations in color-imaging applications (Zhang and Wandell, 1996; Zhang et al., 1997). Hence, the spatial resolution of a neural population should serve as a useful marker for identifying the population of neurons carrying the opponent-colors signals. Neurons carrying the blue-yellow opponent colors image should have relatively large spatial receptive fields, and their receptive field centers should sample the retinal image

FIGURE 20.4 A geometric description of colored stimuli that appear neither red nor green. (A) The test stimulus is a square patch shown on a uniform background. The background is plotted at the origin of the three-dimensional coordinate system. The test stimulus is represented in a three-dimensional color space in terms of the intensities of the three display primaries relative to the background. The arrows on the three

axes indicate the direction of increasing intensity. (B) A surface passing through red-green equilibrium stimuli is shown from four separate views. Stimuli represented on the surface appear blue, yellow, or achromatic. The surface is shaded with these colors to provide a rough guide about their color appearance. (Source: Chichilnisky and Wandell, in press.)

sparsely. Neurons carrying the light-dark image should have small receptive fields and sample the image finely. Neurons carrying red-green information should have a representation intermediate between the other two populations.

CONTRAST, ADAPTATION, AND CONSTANCY A third fundamental aspect of color is that appearance depends strongly on the spatial and temporal context (see, e.g., figure 20.1). The significance of the spatial and temporal context for color appearance judgments represents an important part of the computational structure of the visual pathways.

Various contextual conditions influence color appearance, and several of these conditions have been given special names. Changes in appearance caused by the immediately surrounding spatial region are usually

called *contrast* effects. Appearance effects caused by the eye's adaptation to large, steady backgrounds are called *color adaptation* effects. Appearance shifts caused by changes in the ambient illumination used to view a collection of surfaces are called *color constancy* effects. These stimulus conditions are commonly separated in the literature; but, there is no powerful evidence to show whether these effects are produced by different or similar neural mechanisms.

As stimulus conditions, color adaptation and color constancy have much in common. Both are appearance changes caused by a contextual shift that is spread over large regions of the image and that is stable across time. One important difference between the two conditions is that adaptation is usually associated with conditions in which the target is presented on a uniform background, whereas color constancy involves a patterned background.

FIGURE 20.5 Comparison of red-green and intensity spatial-contrast sensitivity functions. The filled symbols show contrast sensitivity measurements made using stimuli visible mainly to the red-green opponent-colors mechanisms. The data from Anderson, Mullen, and Hess (1991; inverted triangles) and Sekiguchi, Williams, and Brainard (1993; circles) show absolute contrast. The data from Poirson and Wandell (1993; squares) were obtained using a method that does not permit estimation of the absolute sensitivity. These data have been shifted vertically and should be compared only with respect to the falloff in sensitivity. Measurements by Sekiguchi, Williams, and Brainard, and Anderson, Mullen, and Hess compensated for the chromatic aberration of the eye. The Poirson and Wandell measurements did not, but at the relatively low spatial frequencies (below 7 cpd) where the three data sets overlap, red-green chromatic aberration is not a large factor (Marimont and Wandell, 1993). The open circles show contrast sensitivity measurements from three observers to light-dark patterns (Sekiguchi, Williams, and Brainard, 1993). The shaded curves were drawn by hand to emphasize the higher spatial resolution of the light-dark variation measurements.

Given the significance of edges for visual perception, this difference may be important. There is no widely agreed upon method for incorporating both pattern and illumination variation in a single theory. But, some general rules have been observed in cases in which there are relatively few edges in the image and the main effects we must explain are the change in the characteristics of the illumination.

The visual pathways adapt to illumination level changes that span many orders of magnitude and very large changes in the illuminant spectral power distribution. Thus both the overall level of absorptions and the relative cone absorption rates from a surface change under different illuminants. In recent years, a number of studies have shown that the appearance changes caused by changes in the intensity or spectral composition of a uniform background can be approximated by simple rules that modestly extend a proposal from J. von Kries, made in the early 20th century, and

sketched in figure 20.6 (see color plate 8) (von Kries, [1902], 1970).

Consider the simple visual stimulus shown in figure 20.6. The stimulus comprises a uniform background field and a superimposed target. In this case the target is shown as an increment, though in other cases it might be a decrement of the mean field. Modern explanations of von Kries adaptation explain how the background and target interact by assuming that based on spatial and temporal properties the target causes one signal in the photoreceptor array, shown by the main signaling path in the figure. Photons from the background establish the gain, say G_L , G_M , and G_S of the three cone pathways in the main signaling path. For example, increasing the background absorptions in the L cones reduces the gain in the L cone signal.

It is worth spending a moment to consider the implications of this hypothesis rigorously. Stating the rule using symbols is important because the rule contains some surprising subtleties. Suppose that a target t is presented on a background B . Suppose that the background causes a mean level of cone absorptions (L , M , S) which must be

FIGURE 20.6 Schematic of the von Kries model of adaptation. The stimuli are shown as a uniform background field and a small incremental test. Light from the background establishes the gain of the cone signals. Light from the test perturbs the cones. In this version of von Kries adaptation, only background photons absorbed in the L cones influence the gain of the L test signal, and incremental and decremental signals are treated the same. Neither of these assumptions is precisely correct (e.g., Chichilnisky and Wandell, 1996; Mausfeld and Niederee, 1993).

all positive. The target causes a change in the mean level of (l, m, s) , and these values may be negative, positive, or zero. Von Kries suggested that *any* target t seen on background B will match a second target $t' = (l', m', s')$ seen on a second background, $B' = (L', M', S')$ when the target cone absorptions are related by

$$l'/l = G_L / G_{L'}, \quad m'/m = G_M / G_{M'}, \\ s'/s = G_S / G_{S'}$$

One important part of this hypothesis is as follows: The cone absorptions ratios, say l'/l , are the same for any pair of matching lights seen on backgrounds B and B' . Hence, many different matches can be predicted once we know the scalar values associated with each cone class. The von Kries hypothesis has been tested on several occasions and serves as a good approximation (Bäuml, 1995; Brainard and Wandell, 1992; Chichilnisky and Wandell, 1995).

There is a second important part of the hypothesis that has been rarely studied: How do the gain values, G_L , depend on the background photon absorptions? As the hypothesis is drawn, the value of G_L depends only on the L cone signals. Hence, with this form of the hypothesis, test matches can be predicted by scaling within cone types. It may be the case, however, that the gain values depend on the backgrounds in more complex ways.

The two parts of von Kries's hypothesis are open to empirical examination. When measured on simple, uniform backgrounds, the first part of von Kries's hypothesis holds well for decremental targets and coarsely for all targets. Significant improvements in the predictions of color matches can be obtained by applying different rules to incremental and decremental test targets (Chichilnisky and Wandell, 1996; Mausfeld and Niederee, 1993). The further problem of understanding how the gain factors depend on the spatial pattern of the background or the scene interpretation is not understood.

While open problems remain, enough is known about adaptation on uniform backgrounds so that one can make preliminary comparisons between neural and behavioral measurements. The predictions of von Kries's adaptation are powerful, and we may find that not all neural substrates follow its form. Hence, von Kries can be very helpful when we seek those neural substrates that mediate color appearance.

The neural basis of color appearance

Two main hypotheses have been proposed concerning the link between neural activity and color. One hypothesis emphasizes the flow of information from the retina into cortex. The second emphasizes regions in cortex that may play a special role in color perception.

RETINAL ORIGINS Information is sent from the retina to cortex along several distinct populations of neurons, or pathways. These pathways can be distinguished based on the morphology of the cells, their connections within the retina, and their central projections (see figure 20.7). At present, three fundamentally different pathways have been clearly established.

The *P pathway* leaves the retina via the midget ganglion cells. These cells comprise both on- and off-center neurons, and both on- and off-center cells are driven by the single foveal L and M cones. Based on anatomical studies, it appears that the S cones contribute only to an off-center midget ganglion cell (Klug et al., 1993). It appears, though is not yet certain, that the opposing surround signal is controlled by signals from a mixture of the other cone types (Sterling, 1998; but see Reid and Shapley, 1992). The midget ganglion cells project to the parvocellular layers of the lateral geniculate nucleus, and then to layer 4Cb of primary visual cortex.

The *M pathway* leaves the retina via the parasol cells. These neurons project to the magnocellular layer of the LGN. The L and M cone signals contribute with a common sign to both the center and surround responses of neurons in the M pathway. The output of the parasol cells is sent to layers 4Ca and 4B of primary cortex.

The *K pathway* leaves the retina via the *small bistratified retinal ganglion cells*. These neurons receive an excitatory S cone center and an inhibitory L and M cone surround. They project to *koniocellular* layers of the lateral geniculate nucleus, layers that fall in between the parvocellular and magnocellular layers. The neurons in the koniocellular layers project to the superficial layers of visual cortex.

The receptive field and anatomical connections of neurons within these pathways suggest that each has different specializations for transmitting color information. The clearest association is between the K pathway and blue-yellow color appearance. In addition to their opponent-colors signal between the S and (L,M) cones, these neurons also have low spatial resolution (Dacey and Lee, 1994; Sterling, 1998).

It is often said that color is coded by the P pathway, and luminance is coded in the M pathway (e.g., Spillmann and Werner, 1990). The principal experimental evidence for this hypothesis is that foveal midget ganglion cells' centers are driven by signals from a single cone while the surround is driven by an opposing signal that includes the other cone type. Thus, an L cone center midget cell receives an opposing M cone signal from the surround. The opponency between the L and M cone signals can be measured using large stimuli that cover both the center and surround of the receptive field (Derrington, Krauskopf, and Lennie, 1984). Neurons in

Pathway properties					
	Cone inputs	Ganglion cell type	LGN layer	V1 input layers	
Pathway	P	central: single L, M, S center mixed surround peripheral: mixed center mixed surround	midget	parvocellular	4Cb
	M	LM center and surround	parasol	magnocellular	4Ca
	K	S on LM off	small bistratified	koniocellular	2,3

FIGURE 20.7 Some properties of the parvocellular, magnocellular, and koniocellular pathways.

the M pathway are not a candidate for representing an opponent-colors signal because they receive a mixture of L and M cone signals in both the center and the surround. Moreover, their properties seem very well suited to carrying high-temporal-frequency information called the *luminance* signal (Lee et al., 1990; but see V. Smith et al., 1992).

There are some problems with this segregation of tasks between the P and M pathways. First, the number and spacing of the mosaic of neurons making up the P pathway is significantly higher than any other retinal mosaic. In the fovea, for example, each cone sends its output to two neurons in the P pathway (one on- and one off-signal). In fact, the midget ganglion cell mosaic that carries the P pathway signal contains 70% of the 1.25 million human retinal ganglion cells (Rodieck, 1998). Consequently, this mosaic is the only one that can represent the high-resolution signal used for achromatic vision. Second, it seems likely that neurons in the K pathway carry blue-yellow signals. This pathway contains a full representation of the visual field, and the spatial receptive field of the pathway matches the blue-yellow signal well. Third, it is odd to argue that the P pathway represents all of blue-yellow color vision given that it contains only an off-center S-cone-driven cell type and the primary on S-cone signal exits via the K pathway.

At present, there appear to be several possibilities concerning the distribution of color signals. First, the blue-yellow signals may be carried on both the P and K path-

ways. Second, a new retinal pathway carrying the red-green signals may be found. Third, the signals within the P pathway may code both achromatic and red-green signals, and the perceptual red-green representation may be formed through a recombination of these signals in cortex. For example, if P-pathway neurons with L and M cone inputs can be distinguished at the level of cortex, then P-pathway signals could be recombined to create both a light-dark and a red-green representation (Ingling and Martinez, 1983; Lennie, Krauskopf, and Sclar, 1990). What the basis for this discrimination between these types of neurons might be, and how the cortical creation of achromatic and red-green signals can be integrated with other novel cortical receptive field properties such as direction selectivity, orientation, and disparity tuning, remain to be worked out.

CORTICAL CENTERS The second widely discussed hypothesis about the neural basis of color is that there is a cortical “color center.” A cortical center for a perceptual feature, such as color or motion, means that visual experience of that feature is represented by the activity of the neurons within that center (Zeki, 1990, 1993).

In monkey, two cortical locations have been suggested for a putative cortical color center. Zeki has argued that area V4 is the color center because single-unit recordings in area V4 covaried with color appearance, and not the wavelength composition of the test light (Zeki, 1993). These measurements have not been re-

peated, and there has been some disagreement concerning V4's role in color (Schein and Desimone, 1990). For example, Cowey and Heywood (1995) have convincing evidence that area V4 is not essential for color constancy, an important appearance task. They suggest that processing in a nearby area, TEO, is essential.

The modern focus on a human color center is rooted in a seminal paper by Meadows (1974), who reviewed descriptions of individuals with cerebral disturbances of color appearance. Several different types of disturbances exist, and he sketched a pathway and lesion sites where damage might impair performance on several different types of color tasks, including discrimination and appearance language. Human neuropsychological and neuroimaging measurements suggest that damage to a cortical region on the ventral surface of the occipital lobe, in the fusiform gyrus, interferes with normal color processing (Meadows, 1974; Zeki et al., 1991). Neuroimaging studies about this hypothesis are reviewed in the next section.

fMRI measurement methods

By juxtaposing the retinal and cortical hypotheses, one can see that to understand the neural basis of color appearance requires tracing the flow of information from retina through cortex. Selecting stimuli that preferentially stimulate one retinal pathway or another, and then measuring the color responses across cortex, can provide important data for a general theory of the neural basis of color appearance. But, how can we trace the neural activity of the color pathways in the human brain?

Functional magnetic resonance imaging (fMRI) is a neuroimaging method that can be used to make inferences about the neural activity in the alert, performing human brain. The physical basis of the method, as well as some recent advances, are reviewed elsewhere (Moseley and Glover, 1995; Tootell et al., 1996; Wandell, 1999). Briefly, the fMRI signal is an indirect measure of neural activity. The fMRI signal varies as a function of the local blood oxygen content which, in turn, covaries with modulations in the neural activity. In some portions of the brain, particularly near primary visual cortex, changes in blood oxygen mirror the spatial pattern of neural activity at a spatial resolution of less than 2 mm (Engel, Glover, and Wandell, 1997). The signal-to-noise ratio (SNR) of the fMRI signal is somewhat higher than earlier neuroimaging methods, and it can be used to measure stimulus-response functions of active cortical regions in the brains of individual subjects.

To integrate fMRI measurements with the extensive literature on the activity of single units in monkey brain,

it is useful to collocate the neuroimaging measurements with visual areas. The spatial resolution of fMRI and certain advances in visualization methods have made it possible to identify retinotopically organized visual areas in individual observers' brains (DeYoe et al., 1996; Engel, Glover, and Wandell, 1997; Sereno et al., 1995; A. T. Smith et al., 1998). Hence, the neuroimaging results can be compared to single-unit measurements from corresponding areas in animal models.

Two developments have made identification of retinotopically organized areas possible. First, a simple class of stimuli have been developed to permit efficient measurement of the retinotopic organization in several visual areas (Engel et al., 1994). Second, novel methods for visualizing the spatial distribution of activity on the cortical surface have been developed (Dale and Sereno, 1993; DeYoe et al., 1996; Drury et al., 1996; Engel, Glover, and Wandell, 1997; Goebel, 1996; Teo, Sapiro, and Wandell, 1997). The visualization methods permit one to segment gray and white matter and reconstruct three-dimensional images of the gray/white boundary (figure 20.8A; see color plate 9). Using the segmentation, it has proven useful to create flattened representations of the gray matter in order to appreciate the retinotopic organization (figure 20.8B). In those cases described in the next subsection when a visual area is mentioned, its location was determined using retinotopic mapping and flattened representations.

COLOR FMRI MEASUREMENTS Zeki and colleagues (1991; McKeefry and Zeki, 1997; Sakai et al., 1995) have used both PET and fMRI to measure color-related activity in the human brain. In a widely cited set of papers, they measured the difference in activity caused by an achromatic and colored stimulus (Lueck et al., 1989; McKeefry and Zeki, 1997; Zeki et al., 1991). The achromatic version of the spatial stimulus is shown in figure 20.9A, and the colored version has the same lightness but adds various hues. The initial reports were that "the only area showing a significant change of activity was in the region of the lingual and fusiform gyri. This area lies outside the striate cortex and is the same area implicated in achromatopsia (cerebral color blindness)" (Zeki et al., 1991).

This report was puzzling for the following reasons. The achromatic and colored stimuli have equal achromatic signals but different opponent-colors signals. Hence, if we accept the logic of the subtraction methodology, comparisons of the activity caused by the two stimuli should produce activity in all brain regions that respond to opponent-colors signals. The absence of an opponent-colors signal in early cortical areas is puzzling because the parvocellular and koniocellular pathways

FIGURE 20.8 Methods of visualizing the human brain. (A) A three-dimensional rendering of the gray/white boundary of a human brain is shown. The rendering was created by segmenting gray and white matter and creating a connected representation of the gray matter (Teo, Sapiro, and Wandell, 1997). This medial view shows the location of the calcarine (Ca) and parieto-occipital (PO) sulci. This image was created using software developed by R. Taylor in our laboratory. (B) Distances within the connected gray matter can be measured using Dijkstra's algorithm. From these distances, it is possible to create a flat-

tened representation of the gray matter that minimizes the difference between distances measured along the curved gray matter surface and distances on the flattened representation. The underlying gray image represents the gray matter, shaded so that light and dark measure the position along the medial to lateral axis. The colored overlay shows the retinotopic organization with respect to distance from fixation (see the legend at the lower left). A description of the methods as well as software for segmenting and flattening can be obtained from the web site <http://white.stanford.edu/wandell.html>.

should respond to such a signal, and these pathways represent a large fraction of the neurons in primary visual cortex. Why was their response not measured? The absence of a signal in primary visual cortex poses the further question of how these opponent-colors signals reach the fusiform gyrus on ventral occipital surface.

This puzzle has been solved by new results from several laboratories showing that opponent-colors signals can be measured in early visual areas (e.g., Kleinschmidt et al., 1996; Engel, Zhang, and Wandell, 1997; McKee-fry and Zeki, 1997; Hadjikhani et al., 1998). For example, Engel, Zhang, and Wandell (1997) showed that for

certain stimuli, the most powerful responses in area V1, per unit cone contrast, are caused by lights that excite opponent-colors mechanisms.

Figure 20.10A shows the color tuning measured in area V1 using a contrast reversal rate of 1 Hz and with the spatial pattern shown in figure 20.9B. The color tuning is plotted using a format that can be compared with behavioral detection thresholds (see figure 20.3). The solid line in the fMRI color tuning curve shows the L and M cone contrast levels that produced the same fMRI signal. The dashed curves are 80% confidence intervals. The isoresponse curve qualitatively matches the

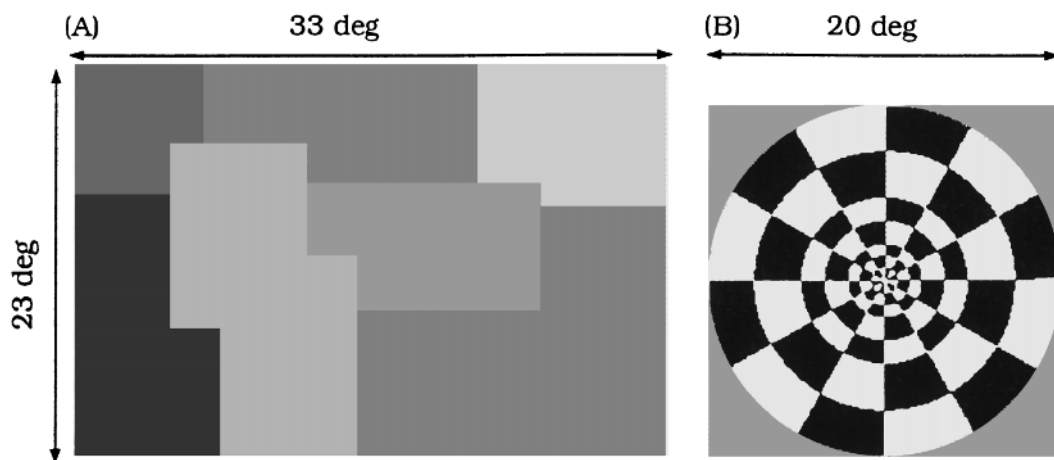

FIGURE 20.9 The spatial structure of (A) the Mondrian stimulus used by McKee-fry and Zeki (1997) and (B) the contrast-

reversing checkerboard used by Engel, Zhang, and Wandell (1997).

FIGURE 20.10 Comparison of the color tuning in area V1 (A) and an active region located in the ventral occipital region, VOc (B). The solid curves show stimuli that evoked an equal fMRI response. Stimuli with opposing L and M cone contrasts

(opponent-colors signals) are more effective at evoking a response than stimuli with covarying L and M cone contrasts. The two regions share a common color tuning; separate measurements suggest that the signal in VOc is slightly stronger.

detection threshold contour measured with the same stimulus.

The original observation of a strong response to chromatic signals within the fusiform gyrus is also confirmed by all groups, and studies of this region may tell us more about the flow of cortical color signals. The retinotopic organization of this region has been probed by McKeefry and Zeki (1997) and by Hadjikhani and colleagues (1998). Both groups find that this location on the ventral occipital surface represents an entire hemisphere. The main difference in their analysis is that McKeefry and Zeki refer to the area as V4, in homology with monkey V4. Hadjikhani and colleagues (1998) suggest the color responsive area falls beyond the fourth retinotopically organized human area and that it should be called V8, and not V4. For the present, the neutral and temporary name *VOc* will be used to refer to the location in ventral-occipital cortex.

Does the color tuning of area V1 differ from that of VOc? Were the opponent-colors signals substantially more powerful in VOc than V1, one might still argue for an enhanced color representation in VOc. Wandell and colleagues (in press) measured the isoresponse curve in VOc to the same stimulus shown in figure 20.9B. For these conditions, they found that the color tuning in VOc and V1 are quite similar. Of course, it remains possible that selecting other spatial patterns or choosing different tasks and viewing conditions will cause differences to emerge.

Measurements with contrast-reversing lights and simple rectangular patterns reveal powerful opponent-colors signals along the pathway from V1, V2, and VOc. But, these are not the only cortical locations that receive opponent-colors signals. Moving stimuli, seen only by

opponent-color mechanisms, evoke powerful activations in motion-selective areas located at the lateral portion of the parieto-occipital sulcus (Ffytche, Skidmore, and Zeki, 1995; Poirson, Baseler, and Wandell, 1997). Hence, cortical responses to opponent-colors stimuli, presumably carried by the parvocellular and koniocellular inputs to cortex, appear widely distributed in cortex. The powerful opponent-colors signal in V1, V2, VOc, and motion-selective cortex represent only a portion of the distribution of color signals in cortex.

The ability to make complete color tuning measurements using fMRI offers us one way to measure cortical signals in human observers. By making these measurements with a broader array of stimuli, we should be able to identify the neural signals that correlate with appearance and understand the computations that take place at different cortical locations.

Conclusions

Several quantitative principles describe human color appearance judgments. Color appearance represents three perceptual dimensions (trichromacy); color appearance computations adjust to changes in the ambient illumination, so that appearance depends more on the relative cone absorptions than the absolute number of absorptions; color appearance is organized into one achromatic and two opponent-colors representations; the spatial resolution of the opponent-colors mechanisms is substantially lower than that of the achromatic mechanism.

Using fMRI, it is possible to make measurements of the color sensitivity in various parts of human visual

cortex. Although visual cortex contains many different signals coding the spectral composition of the retinal image, these signals do not all match the quantitative principles of human color appearance. The signals measured so far may be significant for color appearance, but no region has been clearly identified as a unique color appearance center. Rather, it seems likely that by expanding the range of measurements and comparing the quantitative responses in visual cortex with the fundamental properties of human color judgments, it may be possible to find a series of neural computations that, taken together, result in our experience of color.

21 A New Role for Cortical Area MT: The Perception of Stereoscopic Depth

GREGORY C. DEANGELIS, BRUCE G. CUMMING, AND WILLIAM T. NEWSOME

ABSTRACT Neurons that respond selectively to binocular disparity are widely assumed to play an important role in stereoscopic depth perception, but there is little direct evidence for this presumed link between neurophysiology and perception. Furthermore, it is not clear whether any of the thirty or more known cortical visual areas is specialized for stereopsis, which remains one of the most significant visual functions lacking a clear cortical substrate. We present evidence for a columnar organization of disparity-selective neurons in extrastriate visual area MT of rhesus monkeys. Nearby neurons have similar disparity tuning properties, and the preferred disparity changes smoothly across the cortical surface, suggesting that MT contains a map of binocular disparity. To test whether neurons in this map are involved in depth perception, we electrically stimulated clusters of disparity-selective MT neurons while monkeys discriminated depth in random dot stereograms. Microstimulation systematically biased perceptual judgments of depth toward the preferred disparity of neurons at the stimulation site. These results show that behaviorally relevant signals concerning stereoscopic depth are present in MT. This is the first clear demonstration of specialization for stereoscopic vision in any cortical area.

A central goal of cognitive neuroscience is to reveal how neural activity gives rise to sensory perception. Perhaps the clearest link between a specific perceptual capacity and its cortical substrate has arisen from studies of motion perception and its relation to neural activity in the middle temporal visual area (MT, or V5) of primates. Approximately 90% of MT neurons respond selectively to the direction of motion of a visual stimulus (Dubner and Zeki, 1971; Zeki, 1974), and MT neurons with similar functional properties are clustered together in “columns” such that neurons in each column respond optimally to a particular direction of motion (Albright, Desimone, and Gross, 1984). Numerous experiments have now confirmed that this “functional architecture” for motion direction reflects a prominent role for MT in mediating motion perception. For example, lesions of MT can disrupt motion perception (Newsome and Pare,

1988; Pasternak and Merigan, 1994; Orban, Saunders, and Vandenburg, 1995), and single neurons in MT are exquisitely sensitive to weak motion signals near psychophysical threshold for motion detection (Britten et al., 1992). Moreover, electrical microstimulation of a column of MT neurons can cause monkeys to report seeing the direction of motion encoded by the stimulated neurons, even though the visual display actually contains motion in a different direction altogether (Salzman et al., 1992; Salzman and Newsome, 1994).

In this chapter, we present evidence that MT also plays an important role in stereoscopic vision. Stereopsis is the perception of depth based on small positional differences (binocular disparity) between images formed on the two retinæ. Neurons that respond selectively to binocular disparity were first described three decades ago (Barlow, Blakemore, and Pettigrew, 1967; Pettigrew, Nikara, and Bishop, 1968), and have subsequently been observed in similar numbers in many primate visual areas including V1, V2, V3, MT, and MST (Hubel and Wiesel, 1970; Poggio and Fischer, 1977; Poggio, Gonzalez, and Krause, 1988; Felleman and Van Essen, 1987; Maunsell and Van Essen 1983b; Roy, Komatsu, and Wurtz, 1992). However, evidence for a columnar organization of disparity-selective neurons is limited. Disparity-tuned neurons appear to cluster weakly in cat V1 (Blakemore, 1970; LeVay and Voigt, 1988), and preferred disparity may vary systematically within disparity-tuned subregions of V2 in monkeys and sheep (Hubel and Livingstone, 1987; Ts'o, Gilbert, and Wiesel, 1990; Clarke, Donaldson, and Whitteridge, 1976).

We now show that MT contains a columnar organization for binocular disparity in addition to its well known organization for motion direction. Disparity-selective MT neurons tend to occur in discrete patches, and preferred disparity varies systematically from column to column within these patches. Furthermore, we demonstrate that activation of disparity-tuned columns with electrical microstimulation can influence perceptual judgments of depth in a manner consistent with the disparity tuning of the stimulated neurons. Thus, disparity-selective MT neurons appear to play an important role in stereopsis.

Clustering of disparity-selective neurons in MT

If MT contains an organized map of binocular disparity, then nearby neurons should have similar disparity tuning. To test this possibility, we measured the disparity selectivity of multiunit clusters (MU) and single units (SU) during electrode penetrations through MT. In these experiments, two monkeys (S and P) were simply required to maintain fixation on a small spot of light while a moving random-dot pattern appeared over the multiunit receptive field (RF). Location, size, direction, and movement speed of the pattern were tailored to the preferences of the neurons at each recording site. The horizontal disparity of the moving dots was varied by rendering them in depth as a red/green anaglyph on a standard CRT display (frame rate = 60 Hz). Outside the RF, the remainder of the visual display was filled with zero-disparity dots, which were replotted randomly at 20 Hz to produce a twinkling background. This zero-disparity background helped maintain the monkey's eye vergence at the depth of the fixation point. Vergence angle was monitored in monkey S with the use of binocular scleral search coils (Robinson, 1963; Judge, Richmond, and Chu, 1980), and there was no systematic dependence of vergence on the disparity of the dots.

Figure 21.1 shows MU (filled circles) and SU (open circles) responses measured simultaneously from a single microelectrode. Action potentials from the SU were excluded from the MU response, ensuring that the MU activity arises from several other nearby SUs.¹ The MU response is clearly tuned for disparity, suggesting that its constituent SUs have a similar disparity preference. This conclusion is further supported by the close agreement in shape between the MU and SU tuning curves. Although the SU response is more strongly modulated by disparity, both curves exhibit peaks and troughs at similar disparities. This correspondence between MU and SU tuning curves is typical of most of our recordings in MT.

To quantify this relationship, we fitted the disparity tuning curves with a cubic spline interpolation and we extracted three parameters from each tuning curve. A disparity tuning index (DTI) was defined as $1 - (R_{\min} - S)/(R_{\max} - S)$, where R_{\max} is the maximum fitted response, R_{\min} is the minimum fitted response, and S denotes spontaneous activity (in the absence of a visual stimulus). For sites with significant disparity tuning (one-way ANOVA, $P < .05$), the disparity at which the fitted curve reached a maximum defined the preferred disparity (PD), and the disparity difference between the largest peak and the deepest trough was considered to be the disparity tuning width (DTW).

Across our sample of 110 simultaneous recordings, DTI values for SUs and MUs were significantly corre-

FIGURE 21.1 MT neurons are clustered according to disparity selectivity. Filled circles show MU responses to a drifting random dot pattern (direction = 225° , speed = $2.2^\circ/\text{s}$) with variable disparity. The solid curve is a cubic spline interpolation, and error bars correspond to 1 standard error. Filled circles labeled L and R denote MU responses to the same visual stimulus presented monocularly to either the left or right eye, respectively. The solid horizontal line gives the MU response in the absence of a visual stimulus (i.e., spontaneous activity). Open circles show responses of an isolated SU that was recorded simultaneously with the MU activity (action potentials from the SU were not included in the MU activity). The dashed horizontal line gives the spontaneous activity level of the SU. Note that the tuning of the SU response compares well with that of the MU response, which reflects the combined activity of several nearby neurons. Eccentricity = 6.3° ; RF diameter = 5° . MU response: PD = -0.49° ; DTI = 0.62. SU response: PD = -0.50° ; DTI = 1.05.

lated ($R = 0.67$, slope = 0.79, $P < .0001$). This result permits the important inference that SUs generally exhibit weak disparity tuning at the same recording sites where MU activity is poorly tuned; we can therefore rule out the possibility that flat MU disparity tuning curves arise from a combination of SUs that are well tuned to widely different disparities. At 77/110 sites with significant disparity tuning (one-way ANOVA, $P < .05$ for both SU and MU), there was a strong correlation between SU and MU data with respect to both the preferred disparity ($R = 0.91$, slope = 1.05, $P < .0001$) and the disparity tuning width ($R = 0.76$, slope = 0.87, $P < .0001$). These results indicate that MT neurons are spatially clustered according to their disparity tuning properties, consistent with the notion of a columnar organization for disparity.

Functional architecture for binocular disparity in MT

Having established that disparity-selective neurons are clustered, we investigated the functional architecture of

MT by measuring MU disparity tuning curves at regularly spaced intervals along electrode penetrations through MT. Data were collected at 411 recording sites (241 in monkey P, 170 in monkey S) along penetrations from two different angles. In *oblique* penetrations, we approached MT from the occipital lobe, passing first through the lunate sulcus. Electrodes traveled in a sagittal plane, tilted $\sim 20^\circ$ below horizontal. Thus, our electrode passed through MT at an oblique angle, ranging from $\sim 45^\circ$ to 90° away from the surface normal. Given that MT is organized retinotopically (Maunsell and Van Essen, 1987; Albright and Desimone, 1987) and contains a columnar architecture for direction of motion (Albright, Desimone, and Gross, 1984), we expected both receptive field (RF) position and preferred direction of motion to vary systematically in these penetrations. These known variations could then be used as a reference to evaluate changes in disparity selectivity. In *normal* penetrations, we approached MT from the frontal lobes (near-sagittal plane, tilted $\sim 45^\circ$ below the horizontal), passing first through the central and intraparietal sulci. The electrodes thus entered MT at an angle roughly normal to the cortical surface. In these penetrations we expected RF positions and preferred directions to remain fairly constant, again providing a useful reference for comparison with disparity tuning.

Figure 21.2a shows a sequence of disparity tuning curves measured at 100- μ m intervals along an oblique penetration through MT; figure 21.2b summarizes these data quantitatively. First, note that the disparity tuning was poor both at the beginning and the end of the penetration, but was quite strong in the middle. A similar patchy distribution of disparity-selective responses was observed in many penetrations, suggesting that disparity-selective and -nonselective neurons are spatially segregated within MT. Patches of poor disparity selectivity were short in this penetration, but such patches extended up to 1.5 mm in other oblique penetrations (and were not always at the beginning and end of the penetration). Second, note that the PD changed systematically within the disparity-selective segment of this oblique penetration. Similar gradients of PD from “near” to “far” disparities, or vice versa, occurred along many oblique penetrations, suggesting that MT contains a systematic map of binocular disparities. Finally, as expected for an oblique penetration, the preferred direction of motion changed gradually from one recording site to the next along most of the penetration (figure 21.2b, small arrows), and RF position moved gradually from the lower left quadrant of the visual field up to the horizontal meridian (data not shown).

Figure 21.2c,d shows analogous data from a normal penetration through MT. In contrast to the oblique pen-

etration, the disparity tuning curves were very similar from one recording site to the next (figure 21.2c). The DTI remained roughly constant throughout this penetration, except at the last recording site which was near the boundary with white matter (figure 21.2d). In addition, the PD remained quite constant within a range of near disparities between -0.5° and -0.9° . Both the preferred direction of motion (arrows) and the RF location in space (data not shown) changed little throughout this penetration. We obtained similar results in many of our normal penetrations, including some in which disparity selectivity was poor throughout the penetration.

To summarize these data, we analyzed changes in disparity tuning as a function of distance between recording sites. For 22 oblique penetrations, figure 21.3 (filled circles) shows the mean absolute difference in DTI ($|\Delta\text{DTI}|$) plotted against distance. Data were pooled across the 22 oblique penetrations as follows. For each penetration, we computed $|\Delta\text{DTI}|$ for all unique pairs of recording sites. We then pooled these values across penetrations (for each distance) and plotted the mean $|\Delta\text{DTI}|$ against distance between sites. The data were then analyzed by a two-way ANOVA, with distance and penetration type as the two factors. The mean $|\Delta\text{DTI}|$ increases significantly with distance [$F(9,3060) = 22.5$, $P \ll .001$], indicating that nearby recording sites have more similar DTIs than distant recording sites. At large separations, $|\Delta\text{DTI}|$ for oblique penetrations approaches the value obtained from random pairings of sites (solid line). Similarly, the mean $|\Delta\text{PD}|$ for oblique penetrations (open circles) also increases with distance [$F(9,2708) = 12.61$, $P \ll .001$]. This confirms that there is a systematic map of preferred disparity in MT, with smooth changes from one site to the next.

Among the 14 normal penetrations, both $|\Delta\text{DTI}|$ and $|\Delta\text{PD}|$ tend to increase with distance (filled and open triangles, respectively), as is expected if our “normal” penetrations are not perfectly orthogonal to the cortical surface. At all distances, however, the data from normal penetrations lie well below those from oblique penetrations [$F(1,3060) = 208.9$ for DTI, $F(1,2708) = 122.9$ for PD; $P \ll .001$ for both]. Thus, disparity tuning stays much more constant within normal penetrations, consistent with the idea that disparity-selective neurons are organized in columns that run perpendicular to the cortical surface. A similar finding was previously reported for direction selectivity in MT (Albright, Desimone, and Gross, 1984).

To summarize, the functional architecture for disparity in MT has three main features. First, disparity-tuned neurons are clustered into columns according to preferred disparity. Second, disparity-tuned columns are themselves clustered within MT such that disparity-sensitive

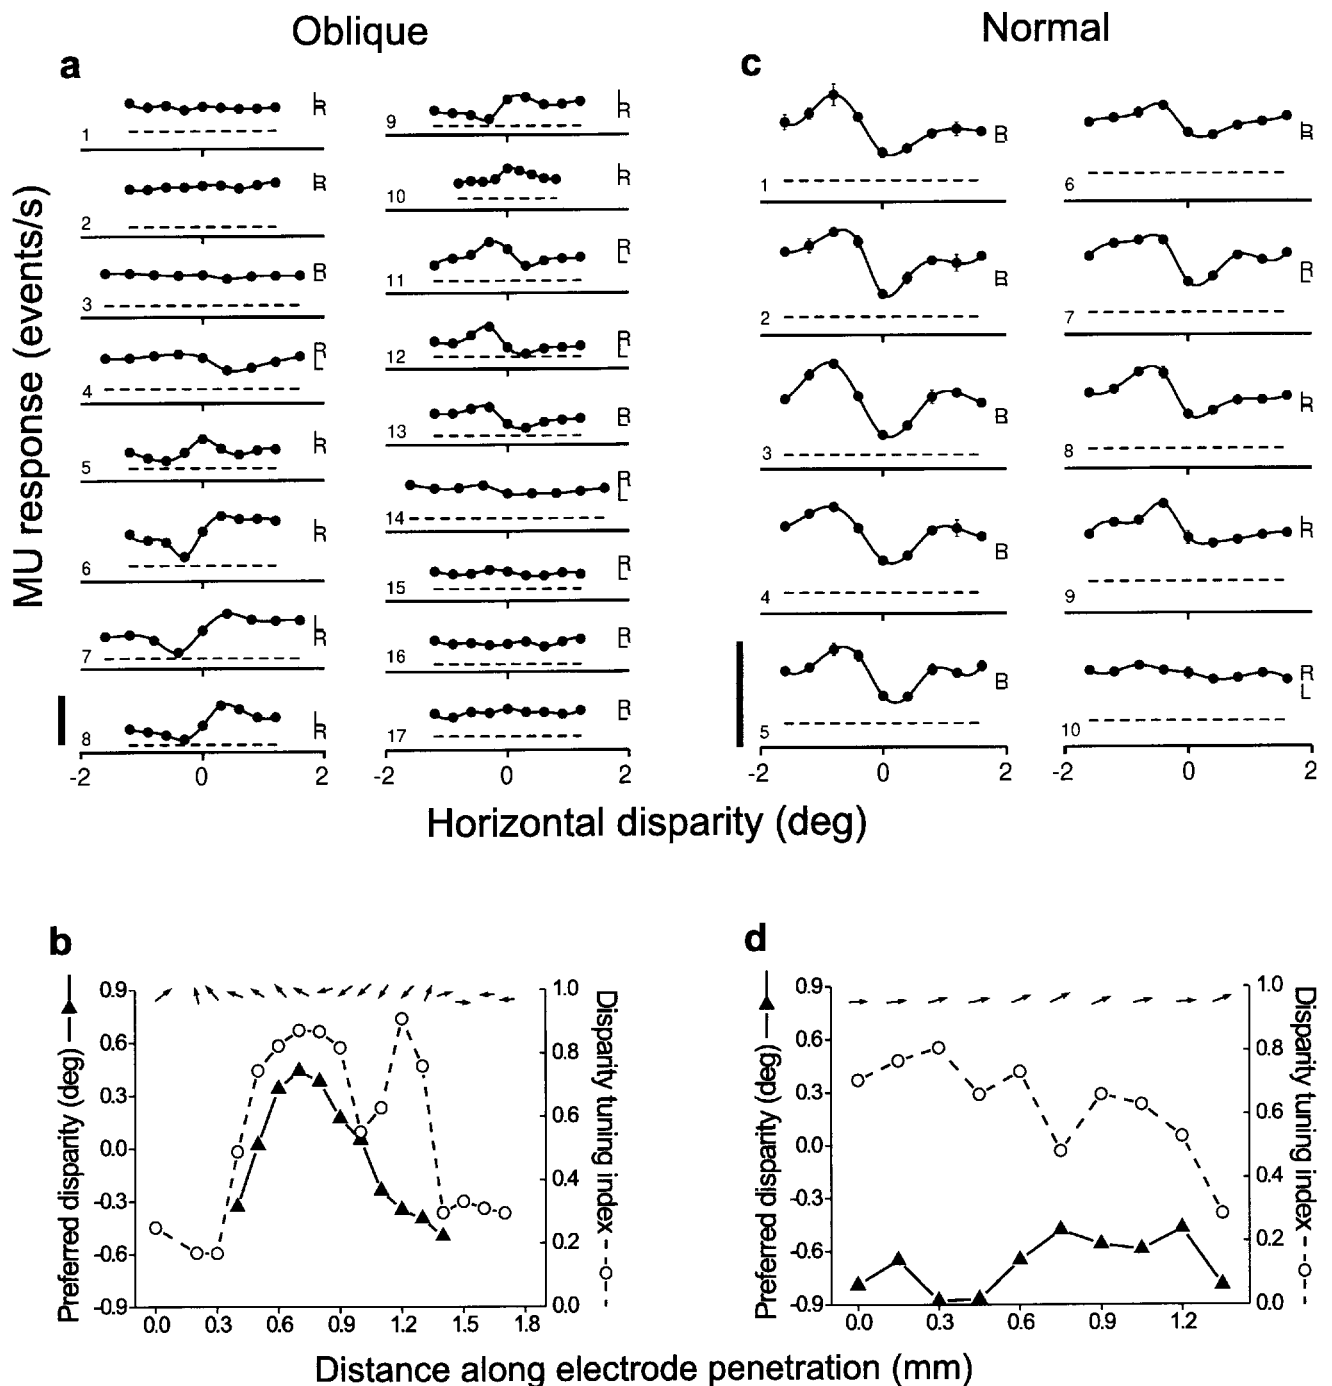

FIGURE 21.2 MT exhibits a columnar architecture for binocular disparity. (a) Sequence of disparity tuning curves recorded at 100- μ m intervals along an oblique penetration through MT in monkey S. Each graph shows the MU response as a function of horizontal disparity. Standard error bars are plotted around each mean, but are generally smaller than the data points themselves. Smooth curves are cubic spline interpolations. Dashed lines represent the spontaneous activity level, and the letters L and R give responses obtained during monocular controls. Height of scale bar = 400 events/s. (b) Quantitative summary of disparity tuning for the oblique penetration illustrated

in part a. Open circles (right axis) plot disparity tuning index (DTI) as a function of distance along the electrode penetration, whereas filled triangles (left axis) plot the preferred disparity (PD) at each recording site (PD is not plotted in cases where there is no significant disparity tuning; ANOVA, $P > .05$). Arrows denote the preferred direction of motion at each recording site. (c) Sequence of disparity tuning curves recorded at 150- μ m intervals along a normal penetration through MT in monkey P. Height of scale bar = 400 events/s. (d) Summary of disparity tuning parameters for the normal penetration in part c. Conventions as in part b.

FIGURE 21.3 Quantitative summary of data from oblique and normal penetrations. Filled symbols show the mean absolute difference in disparity tuning index ($|\Delta DTI|$; left axis) between pairs of recording sites as a function of distance between the sites (filled circles, data pooled across 22 oblique penetrations; filled triangles, data pooled across 14 normal penetrations). Open symbols show the mean absolute difference in preferred disparity ($|\Delta PD|$; right axis) plotted as a function of distance (open circles, data from 22 oblique penetrations; open triangles, data from 14 normal penetrations). Because the number of observations that comprise each data point decreases with distance, data are not plotted beyond a distance of 1 mm. The solid and dashed horizontal lines show the values of $|\Delta DTI|$ and $|\Delta PD|$, respectively, computed from random pairings of recording sites. These are the values that would be expected if there were no functional organization for disparity. Note that the left and right y-axes were scaled (to the nearest round numbers) so that the solid and dashed horizontal lines were roughly superimposed.

patches of cortex are interspersed among cortex that is poorly tuned for disparity (e.g., figure 21.2a,b). Finally, in patches with good disparity tuning, preferred disparity typically varies smoothly from column to column across the surface of MT. Some aspects of the functional architecture for disparity are poorly understood at present. We do not know the actual shapes of the disparity-selective patches, nor how consistently PD is organized within these patches. In addition, we know very little concerning the alignment of maps for direction and for disparity. Optical imaging or 2-deoxyglucose functional mapping studies may help resolve these issues.

Microstimulation of MT biases depth judgments

We next sought to determine whether MT plays a functional role in depth perception. We tested this possibility by applying electrical microstimulation within disparity columns in MT while monkeys performed the stereoscopic depth discrimination task illustrated in figure 21.4. Two monkeys (R and T) viewed a random-dot vi-

sual display in which a fraction of the dots carried a consistent depth signal (“signal” dots), while the remaining dots were randomly scattered in depth (“noise” dots). Signal dots were presented on each trial at a disparity either “near” or “far” with respect to the fixation point. One of the two disparities was the disparity preferred by the MT neurons near the electrode tip, while the other disparity was a nonoptimal disparity. The location and size of the visual stimulus aperture, as well as the direction and speed of the moving dots, were chosen to maximize the MU response. The monkeys’ task was to report seeing near or far depth by making a saccadic eye movement to one of two small saccade targets. By varying the fraction of signal dots in the display (% binocular correlation), task difficulty could be easily adjusted. Importantly, the monkeys were rewarded for reporting the actual depth of the signal dots irrespective of the presence of microstimulation. In these experiments, random-dot stimuli were rendered in depth by presenting stimuli alternately to each eye using LCD shutters synchronized to the frame rate of the CRT display (100 Hz). Again, binocular search coils were implanted in one monkey (R) to detect possible effects of microstimulation on vergence eye movements.

We made oblique penetrations through MT to search for microstimulation sites. An adequate site was considered to be a region where the disparity tuning of MU activity was roughly constant over at least 200–300 μm . Upon identifying a suitable site, we positioned our electrode in the middle of the region of constant preferred disparity for the duration of the experiment. Microstimulation parameters were similar to those used in previous studies from this laboratory (Salzman et al., 1992; Murasugi, Salzman, and Newsome, 1993). The stimulation train consisted of 20- μA biphasic pulses, each consisting of a 200- μs cathodal pulse followed by a 200- μs anodal pulse, with a 100- μs interval between the two. If microstimulation augments the signal carried by the stimulated neurons, and if these neurons provide signals used by the monkey to perform the task, we would expect microstimulation to increase the frequency of perceptual choices toward the depth encoded by neurons at the stimulation site.

Figure 21.5 depicts exactly this result from two microstimulation experiments in MT. Figure 21.5a illustrates the disparity tuning curve for a site that responded optimally to far disparities; the arrowheads indicate the two disparities employed in the depth discrimination task. Figure 21.5b shows how microstimulation at this site affected perceptual judgments. For almost every stimulus condition, the monkey decided in favor of the preferred disparity more often on stimulated trials (filled circles) than on nonstimulated trials

FIGURE 21.4 Depth discrimination task used to measure the effect of microstimulation on depth judgments. (a) Spatial arrangement of the fixation point, visual stimulus, and response targets. The shaded circle (not present in actual display) represents the MU RF. A random dot pattern was presented within a circular aperture approximately the same size as the RF. Filled dots denote the image shown to the left eye, and unfilled dots denote the right eye's image. Here, half of the dots are paired with a fixed disparity (signal dots), and the remaining dots have random horizontal disparities (noise dots). (b) Sequence of events during each trial. The fixation point appeared first, and the monkey was required to maintain fixation within a 1.5° window throughout the trial. After the animal fixated for ~ 500 ms, the visual stimulus appeared for 1 s within the MU RF of the recorded neurons. On half the trials, selected randomly, microstimulation was applied concurrently with the dots. Subsequently, fixation point, visual stimulus, and microstimulation were turned off, and two small target disks ap-

peared. The monkey made a saccadic eye movement to the upper target to indicate a far stimulus, or to the lower target to indicate near. (c) Top-down view of the visual stimulus. On each trial, signal dots appeared at either of two fixed disparities, one near and one far (short horizontal line segments). One disparity (far, in this example) was chosen to be optimal for the recorded neurons (RF shown shaded); the other disparity was chosen to be nonoptimal. Here, the visual stimulus consists of 50% signal dots and 50% noise dots. Task difficulty was modulated by varying the proportion of signal dots in the display (i.e., percent binocular correlation). Signal and noise dots moved with a velocity (direction and speed) that was optimal for the neurons at the electrode tip. Dots situated along the plane of fixation, but outside the stimulus aperture, were stationary and provided a zero-disparity background. These background dots were plotted at random positions on each trial, and appeared simultaneously with the fixation point. (Adapted from DeAngelis, Cumming, and Newsome, 1998.)

(open circles). This bias toward the preferred disparity is evident as a leftward shift of the psychometric function. We considered the magnitude of this shift to be the horizontal offset between sigmoidal curves fitted to the data points (using logistic regression). This shift was measured as the distance between the two curves at the level of 50% preferred decisions. The effect illustrated in figure 21.5b was equivalent to 22.5% correlated dots, a nearly modal effect for monkey R.

Figures 21.5c and d show similar data from an experiment performed on monkey T. Neurons at this stimulation site responded best to near disparities, as illustrated in figure 21.5c. Consistent with the MU disparity tuning, microstimulation at this site induced a strong choice bias toward the near disparity. The resulting shift of the psychometric function was equivalent to 57.6% correlated

dots, the largest effect that we have observed in any of our experiments.

Figure 21.6 summarizes results from 65 microstimulation experiments. The scattergram plots the amplitude of the microstimulation effect against the disparity-tuning index measured at each stimulation site. Positive values on the ordinate correspond to leftward shifts of the psychometric function, that is, shifts *toward* the optimal disparity of the stimulation site. Filled symbols indicate statistically significant effects (logistic regression, $P < .05$), which occurred in 43/65 experiments. Among the significant effects, 42/43 were toward the depth preferred by neurons at the stimulation site, the one exception being a site with poor disparity tuning. The histogram at the right depicts the same data collapsed across DTI.

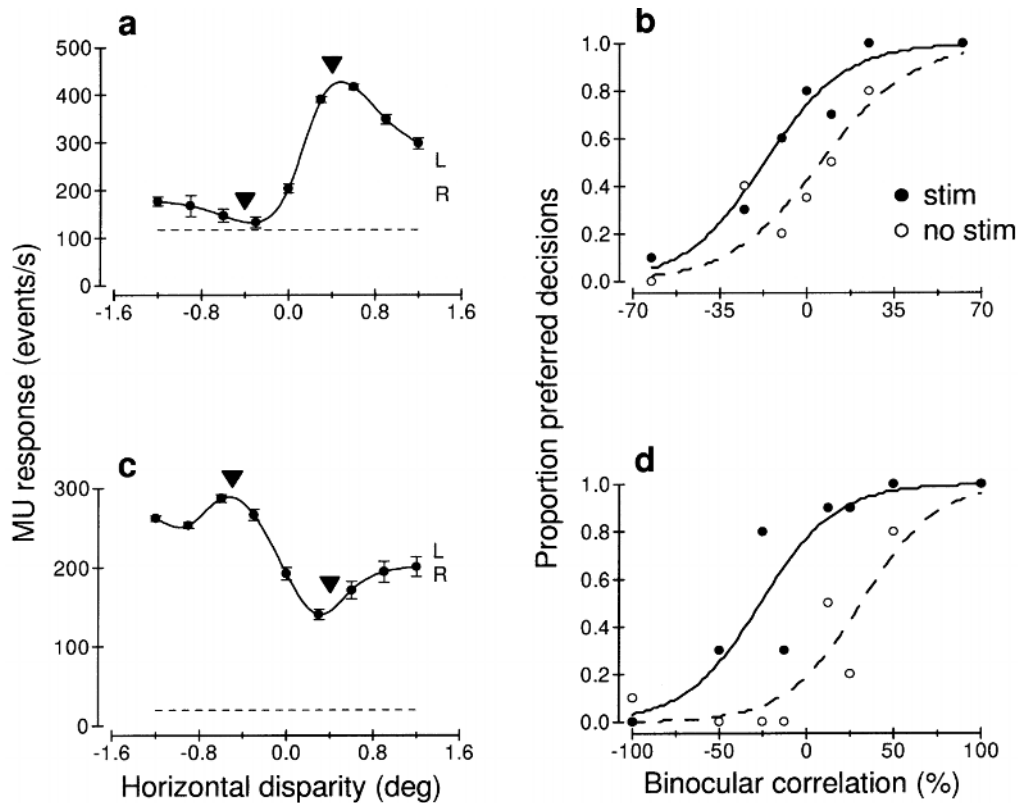

FIGURE 21.5 Microstimulation of MT biases depth judgments. (a) Disparity tuning of MU activity at a site in monkey R preferring far disparities. Arrowheads denote the two disparities used in the depth discrimination task; other conventions as in figure 21.1. (b) Effect of microstimulation on depth judgments for the site depicted in part a. The abscissa represents the strength of the depth signal in percentage of binocularly correlated dots (i.e., percent signal dots). Positive values indicate that signal dots were presented at the preferred disparity (far) of the recorded neurons; negative values correspond to signal dots presented at the nonoptimal disparity. The ordinate is the proportion of decisions that the monkey made in favor of the preferred disparity (each point represents 10 trials). Filled and open circles show psychometric functions obtained during

trials with and without microstimulation, respectively. Each curve was fitted with a sigmoidal function using logistic regression. The net effect of microstimulation was a leftward shift of the psychometric function equivalent to 22.5% correlated dots, and the effect was highly significant ($P < .005$), as determined from logistic regression based on maximum likelihood estimation (Cox and Snell, 1989). (c) Disparity tuning of MU activity at a near-tuned site in monkey T. (d) Effect of microstimulation at the site for which tuning is shown in part c. The leftward shift induced by microstimulation at this site was equivalent to 57.6% correlated dots (logistic regression, $P < .0001$). (Reprinted with permission from DeAngelis, Cumming, and Newsome, 1998.)

The amplitude of the microstimulation effect was significantly correlated with the DTI measured at the stimulation site ($R = .48$, $P < .005$ for monkey R; $R = .45$, $P < .01$ for monkey T). Statistically significant microstimulation effects were generally limited to sites with moderate to strong disparity selectivity. This correlation further demonstrates that microstimulation effects are quite specific; stimulation at sites with weak disparity tuning produces weak effects on depth perception.

Although microstimulation often produced a significant leftward shift of the psychometric function, the slope of the psychometric function changed significantly in only 4/65 experiments (logistic regression, $P < .05$). The average slope ratio (stimulation/no stimulation) of 0.97 did not differ significantly from 1.0 (t-test, $t = -0.68$,

$P > .5$). Thus, microstimulation produces a choice bias toward the preferred disparity without compromising perceptual sensitivity to small variations in binocular correlation.

Microstimulation effects with stationary stimuli

In the experiments described thus far, the motion of the random dots was in the preferred direction of neurons at the stimulation site. Because MT is widely thought to be more important for the analysis of moving than stationary stimuli (Allman, Miezin, and McGuinness, 1985; Albright, 1993), we tested whether the effects of microstimulation on stereo judgments were limited to moving stimuli. After a modest training period, monkey R was

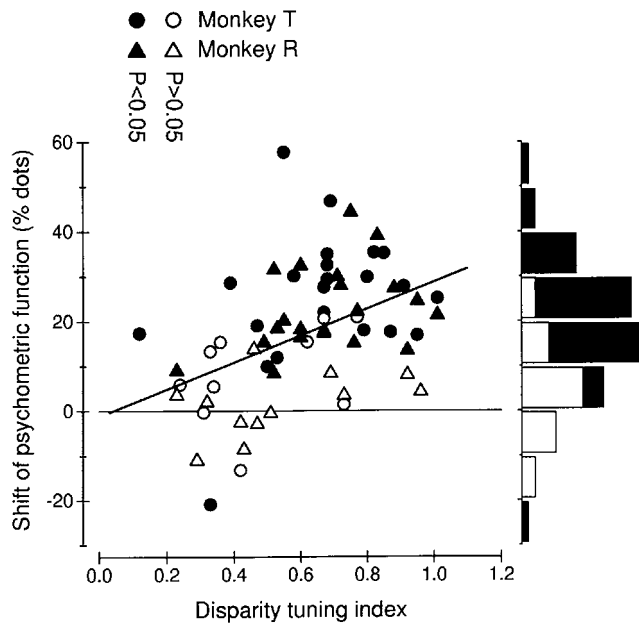

FIGURE 21.6 Summary of microstimulation effects for 65 experiments from two monkeys. The scatterplot shows the shift of the psychometric function (leftward shifts are positive) plotted against the disparity tuning index of MU activity measured at each stimulation site. Filled symbols denote statistically significant effects (logistic regression, $P < .05$). Triangles and circles denote data from monkeys R and T, respectively. The solid line is the best linear fit to the data (linear regression). On the right the data are collapsed across DTI and plotted as a histogram. (Reprinted with permission from DeAngelis, Cumming, and Newsome, 1998.)

able to perform the depth discrimination task (figure 21.4) with all dots stationary. Thus, image motion on the retina could only arise from small eye movements occurring during fixation.

We performed the stationary-dots experiment at 12 sites in MT where microstimulation generated significant effects on depth judgments when the dots were moving. At 9 of these 12 sites, microstimulation also exerted a significant effect on depth judgments involving stationary dots; judgments in the stationary-dots condition were unaffected at the remaining 3 sites. The mean leftward shift of the psychometric function across all 12 sites was 25.8% for moving dots and 27.9% for stationary dots ($P > .5$; paired t-test). We also measured disparity tuning curves using stationary dots at these 12 sites. All exhibited strong disparity selectivity for stationary dots (mean DTI was 0.93 for stationary and 0.70 for moving dots; $P < .001$, paired t-test), although the overall response level was generally larger for moving dots (371 events/s) than for stationary dots (223 events/s) ($P < .001$, paired t-test). Some of the response to stationary dots was almost certainly driven by small eye movements during fixation.

The experiments described here provide two new lines of evidence that primate area MT is an important processing stage for neural signals related to stereoscopic depth perception. First, MT contains a functional architecture for binocular disparity in addition to its well known architecture for direction of motion: MT neurons are clustered according to their disparity selectivity, and preferred disparities vary smoothly across the surface of MT within the disparity-tuned patches. To our knowledge, this is the first clear, quantitative evidence for a systematic map of preferred disparity in primate visual cortex (but see Hubel and Livingstone, 1987; Ts'o, Gilbert, and Wiesel, 1990). Second, microstimulation of disparity columns in MT can bias stereoscopic judgments of depth, and the direction of the bias (near or far) is predictable from the disparity tuning of neurons at the stimulation site. Thus the disparity signals carried by MT neurons are an important part of the neural substrate for depth judgments in our task. This finding establishes the first direct link between the physiological property of disparity selectivity and the stereoscopic perception of depth. Note that the existence of disparity selective neurons alone is not sufficient to establish this link, because disparity signals can be used for other purposes such as guidance of vergence eye movements, a possibility strongly suggested by recent experiments on disparity selective neurons in V1 (Cumming and Parker, 1997; Masson, Busetini, and Miles, 1997). It is possible that disparity signals in MT are also used in the control of vergence eye movements, although careful inspection of data from monkey R revealed no effect of microstimulation on vergence.

Previous work has shown that MT is specialized for processing motion information (Albright, Desimone, and Gross, 1993). In fact, MT is often cited as one of the best examples of functional specialization in cortex. Our results show that the role of MT in vision is not limited to motion analysis. This conclusion is emphasized by the fact that many MT neurons exhibit robust disparity tuning in response to stationary random-dot patterns, and that microstimulation biases depth judgments involving stationary dots. Although the vast majority of MT neurons are selective for direction and speed of visual motion (e.g., Maunsell and Van Essen, 1983a), their activity apparently can be used to judge the depth of stationary objects as well (the *retinal image* is not completely stationary, of course, due to small eye movements around the point of fixation). Our findings concerning the role of MT in stereopsis are complemented by recent evidence that MT may also play a role in the perception of depth from motion cues (Bradley, Chang, and Andersen, 1998; Dodd et al., 1997).

Under the conditions of our experiment, which involves large disparities degraded by noise, MT appears to play an important role in depth perception. This does not mean, however, that *all* aspects of stereopsis depend on MT, nor that any *single* aspect of stereopsis depends *entirely* on MT. Consider, for example, that monkeys are capable of discriminating differences in disparity of less than 20 seconds of arc in the fovea (Sarmiento, 1975; Cowey and Wilkinson, 1991) and 1–3 minutes of arc at 5 degrees eccentricity (Pointon, Cumming, and Parker, 1998). By comparison, the disparity tuning of MT neurons is quite coarse (figure 21.2); thus, discrimination of fine disparities in our visual stimuli may require other cortical areas where neurons are more sharply tuned for disparity. The involvement of other cortical areas may in part explain why lesions of MT have not revealed a stereo deficit (Schiller, 1993). Broadly based investigations, including single-unit recording, microstimulation, and lesion techniques in a number of visual areas, will be necessary to achieve a comprehensive understanding of the neural basis of stereoscopic vision.

ACKNOWLEDGMENTS We are grateful to Judy Stein and Cynthia Doane for capable technical assistance, and to Andrew Parker, Jon Dodd, Brian Wandell, Jamie Nichols, Eyal Siedemann, Greg Horwitz, and Crista Barberini for critical review of the manuscript. NOTE

1. SU action potentials were identified using a template-matching algorithm implemented by a spike-sorting board; MU activity was recorded by means of a time-amplitude window discriminator. SU action potentials were excluded from the MU activity by setting the upper boundary of the window discriminator well below the peak of the SU action potential. For several experiments, the effectiveness of this approach was confirmed off-line by deliberately editing out any event in the multiunit record that occurred within a 3-ms window centered on each spike from the SU response, thereby eliminating any possible "leakage" of SU activity into the MU response. Analysis of the edited MU records yielded results essentially identical to analysis of the unedited MU records.

22 Effects of Attention on Neuronal Response Properties in Visual Cerebral Cortex

JOHN H. R. MAUNSELL AND CARRIE J. MCADAMS

ABSTRACT While many studies have shown that attention can affect the strength of neuronal responses in cerebral cortex, little is known about whether attention alters the stimulus selectivities of individual neurons. We have examined this question by recording the responses of isolated neurons in area V4 of monkeys while they performed a task that required them to either attend to or ignore the stimulus in a neuron's receptive field. Comparisons of orientation tuning curves measured in the two modes suggest that attention increases responses to all stimuli proportionately, without sharpening the tuning curve. A proportionate scaling of tuning curves without sharpening has also been reported when stimulus attributes such as contrast or color are varied. Thus, it is possible that ascending sensory signals related to stimulus qualities and descending signals related to behavioral state are treated equivalently in visual cortex.

Attention is a critical determinant of what we perceive. At any moment we can give full attention to just a tiny fraction of the available sensory information. Attention often makes the difference between looking and seeing. Major changes in the visual scene can go unnoticed if attention is not allocated to the site of change (see Rensink, O'Regan, and Clark, 1997; Simons and Levin, 1997). Even when changes are detected, responses to a stimulus are slower or less sensitive when attention is directed to some other spatial location or object attribute (see Duncan, 1984; Hikosaka, Miyauchi, and Shimojo, 1993; Egeth and Yantis, 1997).

In neurophysiological studies, attention has been shown to affect how sensory information is processed in the cerebral cortex. The influence of a subject's level of vigilance on the responses of cortical sensory neurons was obvious in some of the earliest single-cell recordings made from awake animals (Hubel et al., 1959). While some of these effects may be widespread, nonspecific

modulations related to the level of arousal, neurons in every part of the visual cortex have been shown to be influenced in highly selective ways that depend on the behavioral significance of the stimulus in their receptive field (see Colby, 1991; Colby, Duhamel, and Goldberg, 1993; Desimone and Duncan, 1995).

Figure 22.1 shows data from our laboratory that illustrate the effects of attention on the activity of a cortical neuron. Responses were collected from a directionally selective cell in the medial superior temporal area (MST) in a monkey that watched two dots move back and forth on a screen (Treue and Maunsell, 1996). Only one of the dots fell in the receptive field of the neuron. On a given trial, the animal was instructed to attend to one of the two stimuli. The animal's eye position was monitored, and the animal was required to attend to the selected dot without looking at it directly, holding its gaze fixed on a small fixation point. In this way we could ensure that the retinal stimulation was the same whether the animal directed its attention to one dot or the other. Like many neurons in the later stages of visual cortex, this cell responded much more strongly to the receptive field stimulus when the animal paid attention to that stimulus than when the animal focused its attention on the other stimulus. Because the retinal stimulation was the same in both conditions, we attribute the difference in the neuron's response to whether the animal was attending to the stimulus inside its receptive field. Thus, this neuron did not signal the motion of any stimulus on its receptive field; rather, it selectively signaled the motion of stimuli to which the animal was attending.

Many studies have shown that attention can change the strength of neuronal responses, in most cases causing cells to respond more strongly when the animal pays attention to the stimulus they represent (see Maunsell, 1995). Little is known, however, about the interactions between attention and the sensory response properties of neurons. Most studies of attention have examined responses to a single stimulus, leaving open the

CARRIE J. MCADAMS Division of Neuroscience, Baylor College of Medicine, Houston, Tex.

question of whether attention alters stimulus selectivity. For example, the data in figure 22.1 show that attention increased responses to motion in the preferred direction for a neuron, but they do not address the question of whether attention changed the directional selectivity of the cell. Sharpening neuronal tuning for behaviorally relevant stimulus dimensions might be a powerful mechanism for improving behavioral detection or discrimination of those stimulus attributes.

We have begun to examine this question by recording the responses of isolated neurons in area V4 of trained monkeys. We selected V4 because it represented a good compromise between earlier stages, in which behavioral modulations are weaker, and later stages, in which tuning curves for simple stimulus dimensions are more diffi-

FIGURE 22.1 Attentional modulation of the responses of a neuron in the medial superior temporal area (MST). The upper panel is a schematic representation of the stimulus configuration. Stimulus 1 was positioned to move back and forth across the center of the receptive field of the neuron being recorded. Stimulus 2 moved back and forth outside the receptive field in the other half of the visual field. Gaze was held on the fixation spot throughout all trials. The subject animal could be instructed to attend to either one of these stimuli by a cue presented at the start of each trial. It was trained to release a lever when the cued stimulus changed its speed. The other stimulus might also change speed, but trials ended without reward if the animal responded to the uncued stimulus. The lower panels show the neuron's responses to the receptive field stimulus sorted according to whether the animal was attending to that stimulus. Each histogram shows the rate of firing as a function of time as the stimuli moved back and forth. The shaded portions are intervals when the stimulus inside the receptive field moved in the direction preferred by the neuron. Each plot is the average of many stimulus presentations. The average rate at which this neuron fired spikes was much greater when the animal was attending to the stimulus in its receptive field, although the retinal stimulation was the same in both cases.

cult to obtain. Because most neurons in V4 are sensitive to the orientation of stimuli in their receptive field, our experiments have focused on the effects of attention on orientation tuning.

Effects of attention on orientation tuning in area V4

TASK DESIGN AND DATA COLLECTION Monkeys were trained to do a task that shifted their attention between two stimulus locations. We used a match-to-sample task in which pairs of stimuli were presented as samples and tests (figure 22.2). The displays were generated on a calibrated video monitor under computer control. The stimuli in one location were grating patterns, while those in the other location were patches of color. On each trial, the animal attended to just one location and used a lever to report whether the sample and test stimuli in that location were the same or different. The location for attention was signaled to the animal using instruction trials in which stimuli appeared in only one location. The animals learned to continue reporting on this location during a subsequent block of trials when stimuli were presented in both locations.

Matches in the two locations were uncorrelated so that the animal got no advantage from attending to or responding to stimuli in the incorrect location. Because the animals got 80–90% of the trials correct, we can be sure that they kept track of the relevant location. There is no way to know whether the animal allocated some attention to the incorrect location, but any attention allocated to the incorrect location should only reduce the modulations in neuronal response that we observed. For that

FIGURE 22.2 The delayed match-to-sample task used to examine the effects of attention in area V4. The stimuli appearing in one location were black and white Gabors that were temporally counterphased at 4 Hz. The stimuli in the other location were two-dimensional colored Gaussians. All stimuli were isoluminant with a midlevel gray background. Pairs of sample and test stimuli were presented for 500 ms and were separated by 500 ms during which only the fixation spot was present. On

each trial the animal was instructed to attend to just one location and to report whether the sample and test stimuli in that location were the same. The correct response to a match was to release a lever within 500 ms from the start of the test stimulus. The correct response for nonmatching stimuli was to keep the lever depressed until the test stimulus was removed (700–1000 ms after its appearance).

reason, the effects we describe here should be considered a lower limit on the full range of attentional modulations of responses.

We monitored eye position and required the animals to perform the task while keeping their fixation within 0.5° of a small spot at the center of the screen. Using controlled fixation, the stimuli could be presented to specific locations on the retinas, and were the same whether the animal attended to one stimulus or the other.

While the animal performed the task, extracellular recordings were made from isolated neurons in area V4. For each cell the stimuli were adjusted so that the grating patterns were centered in the receptive field. The size and spatial frequency of the gratings were optimized for each neuron. Over the course of many trials, we collected neuronal responses to a complete range of grating orientations in two conditions: one when the animal was attending to the grating in the receptive field and reporting on its orientation, and one when it was ignoring the grating and reporting on the color of the other stimulus outside the receptive field. The stimuli were exactly the same in both cases, and the animal's attention was cycled back and forth between the two locations many times during data collection from each neuron.

STRONGER RESPONSES WITHOUT NARROWER TUNING Results from a typical V4 neuron are shown in figure 22.3. Like many neurons in V4, this cell responded more strongly to the grating patterns in its receptive field when the animal paid attention to them. The upper panels show the responses of the cell to selected stimulus orientations. These data, and all others presented here, are responses to the presentation of the sample stimulus. The upper row contains responses collected while the animal was attending to the stimulus, and the bottom row contains responses collected while the animal was ignoring those stimuli and attending to the color patches in the other visual hemifield. Although the neuron responded to the receptive field stimulus in both cases, responses were stronger when the animal was attending to that stimulus (with the possible exception of the least favored orientations, which were inhibitory).

The lower panel in figure 22.3 shows the average rate of firing to each of the 12 stimulus orientations tested. In this and other figures we present responses as the average rate of firing during the stimulus presentation without subtracting the spontaneous rate of firing. The curve through each set of points is the best-fitting Gaussian function. The amplitude of the curve when the animal attended to the stimuli was 26 spikes/s, while that for the ignored stimuli was 18 spikes/s. Because the same stimuli

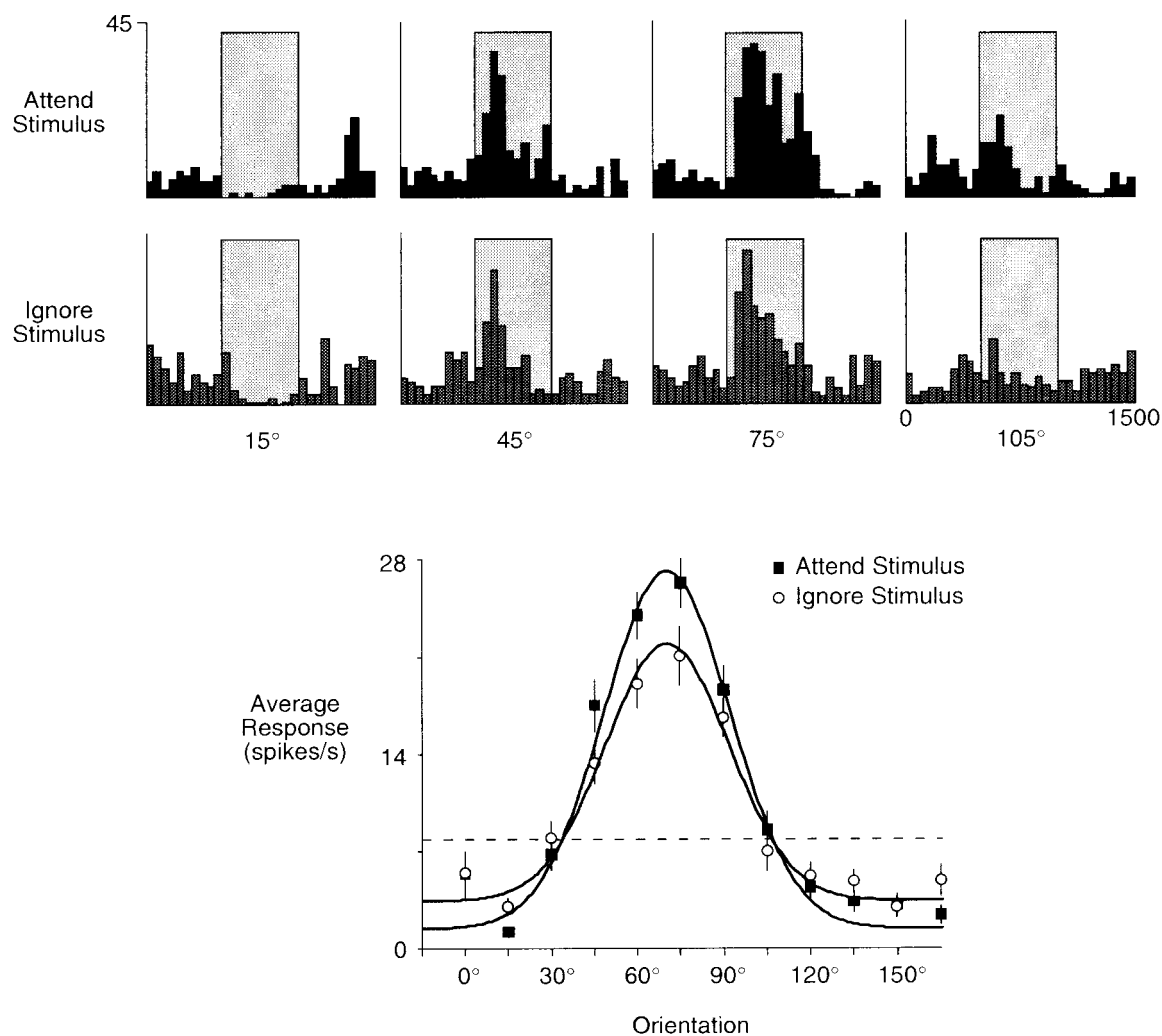

FIGURE 22.3 Effects of attention on the responses of a V4 neuron to oriented stimuli. The histograms in the upper panels plot the response of the neuron to the appearance of the sample stimulus in the receptive field. The pairs of histograms in each column represent responses to 4 different orientations of the Gabor stimulus in the receptive field. The upper row shows responses collected when the animal was attending to the sample stimulus, and the lower row shows responses to the same stimulus was ignored. The shading marks the period when the sample stimulus was present. The axes are scaled in spikes per second (vertical) and milliseconds (horizontal). Each

histogram includes 20 repetitions of the stimulus. The lower panel is a plot average rate of firing as a function of sample stimulus orientation. Filled squares mark responses to attended stimuli and open circles mark responses when the stimuli were ignored. The error bars are ± 1 standard error of the mean. The dashed line represents spontaneous activity. The curves through the data points are best-fitting Gaussians. The neuron was orientation-selective in both cases, but the amplitude of the fitted function, measured from its peak to its baseline, was greater when the animal was paying attention to the stimuli. There was little change in the width (σ) of the fitted functions.

were presented in both conditions, this difference in response can be attributed to differences in the way the animal allocated its attention between the two conditions. A stronger response to attended stimuli has been reported in many earlier studies of V4 (Moran and Desimone, 1985; Haenny, Maunsell, and Schiller, 1988; Haenny and Schiller, 1988; Spitzer, Desimone, and Moran, 1988; Maunsell et al., 1991; Motter, 1993; Motter, 1994a, b; Connor et al., 1996, 1997; Luck et al., 1997).

By measuring responses to different orientations, we can ask whether attention affects the sharpness of orien-

tation tuning for V4 neurons. Although the amplitude of the orientation tuning curves changed for this neuron, there was little difference in the width of the tuning functions. The widths of the fitted functions in figure 22.3, taken as one standard deviation (σ) of the Gaussian, are 30° for the attended stimuli and 31° for ignored stimuli.

An increase in orientation tuning curve amplitude without a change in width was typical for the V4 neurons we encountered. Data from 262 V4 neurons in two monkeys are summarized in figure 22.4. The statistical significance of each Gaussian fit was determined by per-

FIGURE 22.4 Effects of attention on the amplitude and width of orientation tuning curves in V4. For the 197 V4 neurons whose responses to different orientations were well-fit by Gaussian in both task modes, ratios of curve amplitudes and widths were computed for each cell. The median ratio for tuning curve amplitude was 1.24, indicating a systematic increase

in response modulation in V4 with attention. The median ratio for tuning curve width was 1.00. There is no sign of a systematic relationship between the two ratios. The histograms above and to the right of the scatterplot show the distributions for amplitude and width ratios. The medians of each distribution are marked with small arrows.

forming an F-test that compared the goodness of fit to that for a line. Of the neurons recorded, the orientation tuning data for 197 (75%) reached criterion for the Gaussian fit in both the attended and unattended conditions ($p < .05$; median $r^2 = 0.40$). For these neurons, we computed a ratio for the amplitude of the tuning curves for the attended and ignored stimuli. A corresponding ratio was computed for the width of the curves. For the neuron whose responses are illustrated in figure 22.3, the ratio for amplitude was 1.44, and that for tuning width was 1.03. Across the entire V4 population, attention enhanced responses to oriented stimuli (median amplitude ratio 1.24), but there was no systematic effect on tuning width (median width ratio 1.00). The scatterplot reveals no correlation between the effects of attention on the amplitude and width of the orientation tuning curves.

An alternative way to assess the effects of attention on orientation in V4 is to construct population tuning curves. The response functions in figure 22.5 represent the average effect of attention on the responses of individual neurons in that area. These functions include all

the responses collected from the 262 neurons tested in V4. The data points from each cell were shifted left or right to align peak responses at 0° . The data points (and the level of spontaneous activity) were then scaled vertically to bring the peak to 1.0, while the level of 0.0 spikes/s was not moved. Firing rates for each orientation and behavioral state were then averaged across all neurons. The solid curves in figure 22.5 are Gaussian functions that were fitted to the averaged data. The dashed line is the average spontaneous activity. These population tuning curves differ in amplitude by a factor of 1.31, but their widths are the same ($\sigma = 38^\circ$ in both conditions).

MULTIPLICATIVE SCALING OF ORIENTATION TUNING CURVES These results suggest that attention increases the amplitude of orientation tuning curves without systematically changing their width. A question that remains is whether the effect of attention is a multiplicative scaling, such that responses to all orientations are increased proportionately. The amplitude change described above

FIGURE 22.5 Population orientation tuning curves for V4. Responses from all 262 V4 neurons are summarized in these curves. They were constructed by shifting each neuron's tuning curves left or right to bring the preferred orientation to 0°, and vertically to bring the peak of the attended orientation tun-

ing curve to 1.0. Values at each point were then averaged. The curves represent the average effects of attention on orientation tuning within V4. Attention increased the amplitude of the average orientation tuning curve by about 35%, but did not affect the width of orientation tuning (0%).

does not address this issue because the amplitude could increase even if there were no change in the response to the least preferred orientations.

We can assess whether attention causes a proportional increase in responses to all orientations by plotting responses from the condition where the animal was attending to the stimulus against responses when the animal was ignoring the stimulus. If attention increases all responses proportionately, the points should lie on a straight line whose slope gives the proportional change. Figure 22.6 is such a plot. It replots the data from figure 22.5. Each point represents responses to a particular orientation (relative to preferred orientation), with the normalized response to the attended stimulus on the vertical axis and the normalized response to the ignored stimulus on the horizontal axis. The dashed lines are at ± 1 standard error of the mean of spontaneous activity in the two conditions.

The correlation coefficient for these data is 1.00 (0.99 confidence interval: 0.99–1.00). This excellent correlation supports the idea that the effect of attention is a multiplicative scaling of responses. A least-squares regression of the response in the attended condition on the response in the ignored condition gives a line with a slope of 1.31, corresponding to a 31% increase in neural responses when the animal attended to the stimuli in the receptive field. If attention acts by multiplicative scaling of responses, then no-response in one condition should correspond to no-response in the other. The regression line shows that this is the case: It passes through the region representing spontaneous activity in both conditions.

THE MAGNITUDE OF ATTENTION EFFECTS Although some individual neurons were greatly affected by attention, for most the changes in tuning curve amplitude were modest (figure 22.4). Nevertheless, the modulations reported here should not be taken as an absolute indication of the strength of attentional modulations in V4. Measures of human performance show that the processing of irrelevant stimuli can proceed automatically, suffering only when attentional demands are great (Rees, Frith, and Lavie, 1997). Neurophysiological experiments that have varied the difficulty of tasks suggest that the effects of attention covary with difficulty (Spitzer, Desimone, and Moran, 1988; Spitzer and Richmond, 1991). The performance of our animals suggests that they were not greatly challenged by the task they performed (80–90% correct responses). They may therefore have directed some attention to both stimulus locations at all times, only varying the proportion allocated to each site when different locations were cued. This possibility could be addressed in experiments that manipulate attentional load and include more challenging conditions.

The relationship between sensory and attentional signals in visual cortex

CHANGES IN ATTENTION RESEMBLE CHANGES IN STIMULUS PROPERTIES Our results suggest that attention acts to selectively strengthen the responses of cortical neurons that convey behaviorally relevant sensory signals without changing their stimulus selectivity. A multiplicative scaling of tuning curves by attention is in-

FIGURE 22.6 Multiplicative scaling of responses by attention. This scatterplot replots the data in figure 22.5. Each point represents the population average response to a particular orientation (relative to preferred orientation, ± 1 standard error of the mean), with the response to attended stimuli on the vertical axis and the response to ignored stimuli on the horizontal axis. The dashed lines are ± 1 standard error of the mean for spontaneous activity in each condition. As predicted by multiplicative scaling, responses are highly correlated (correlation coefficient 1.00). The line through the data is a least-squares regression of the attended response on the ignored response. This line has a slope of 1.31. As expected for multiplicative scaling of responses, this line passes through the region representing spontaneous activity in both conditions.

interesting because it resembles the effects of manipulating stimulus qualities. For example, orientation-selective cells generally respond more strongly to brighter stimuli, and orientation tuning curves derived using stimuli of different brightnesses are multiplicatively scaled versions of each other. It is commonly observed that when a neuron is sensitive to two stimulus attributes, manipulating one attribute will multiplicatively scale the tuning curve for the other without changing the steepness of the tuning function. This has been found for many pairwise manipulations: contrast and orientation or direction, contrast and spatial frequency, contrast and temporal frequency, contrast and spatial position, orientation and direction, speed and direction, and spatial frequency and temporal frequency (Ikeda and Wright, 1972; Tolhurst and Movshon, 1975; Dean, 1980, 1981; Holub and Morton-Gibson, 1981; Albrecht and Hamilton, 1982; Sclar and Freeman, 1982; Bisti et al., 1985; Foster et al., 1985; Rodman and Albright, 1987; Skottun et al., 1987; Galli et al., 1988; Hamilton, Albrecht, and Geisler, 1989; Friend and Baker, 1993; Carandini and Heeger, 1994; McLean and Palmer, 1994a, b; Geisler and Albrecht, 1997).

Our results suggest that the interactions between sensory signals and those related to attention may also be multiplicative. Other types of extraretinal inputs to visual cortex also lead to multiplicative scaling of sensory responses: Signals related to the angle of gaze appear to scale receptive field profiles of neurons in posterior parietal cortex (Andersen, Essick, and Siegel, 1985). Thus, it is possible that multiplicative scaling is the normal mode of interaction between all inputs to visual cortex, whether retinal or extraretinal. Mechanisms that would produce multiplicative scalings of response functions have been described (Albrecht and Geisler, 1991; Carandini and Heeger, 1994), and advantages of this property have been discussed (e.g., Pouget and Sejnowski, 1997; Salinas and Abbott, 1997). It is nevertheless fair to say that we lack a good understanding of the significance of this arrangement for processing of information in cerebral cortex.

The phenomenological similarity between the effects of attention and those of sensory signals raises the possibility that attentional inputs to cortex involve neural mechanisms (e.g., circuits, cell types, neurotransmitters) that are similar, perhaps identical, to those used in processing ascending signals from the retinas. For example, neurons in V4 might receive ascending inputs from earlier stages of visual cortex, which convey information about retinal stimulation (contrast, color, orientation, etc.), and descending signals from higher centers, perhaps prefrontal cortex, which convey information about behavioral state (e.g., whether the region within the neuron's receptive field is behaviorally relevant). The origins of these signals would be unknown and irrelevant to the recipient V4 neurons, which would treat all the inputs equivalently in generating their response.

EXCEPTIONS TO MULTIPLICATIVE SCALING Some neurons respond best to different temporal frequencies when tested at different spatial frequencies (Ikeda and Wright, 1972; Foster et al., 1985; Friend and Baker, 1993). Such changes in the preferred stimulus are not consistent with multiplicative scaling of responses. Similarly, shifting the locus of spatial attention within or around a receptive field changes the receptive field profile (i.e., tuning in spatial coordinates; see Moran and Desimone, 1985; Connor et al., 1996, 1997). Shifts in the receptive field profile are also inconsistent with multiplicative scaling.

It is possible that multiplicative scaling is the norm for cortex and that exceptions such as these represent unavoidable consequences of the generation of new response properties. For example, an interdependence between spatial frequency and temporal frequency preferences would be expected for neurons that preferred a

particular speed of motion. If a neuron's best response always occurred at a particular speed, then tests with drifting sinusoidal gratings would yield an optimum temporal frequency that was higher for high spatial frequencies and lower for low spatial frequencies. Such neurons may nevertheless show multiplicative scaling when speed tuning is examined. For example, speed-selective neurons in the middle temporal visual area (MT) do show multiplicative scaling for tuning curves for speed when direction of motion is varied (Rodman and Albright, 1987).

Changes in receptive field profiles associated with local shifts in spatial attention might similarly arise as an unavoidable consequence of the trend toward larger receptive fields in later stages of visual cortex (see Maunsell and Newsome, 1987). The large receptive fields in V4 are constructed by summing signals from neurons in earlier cortical stages, which have smaller receptive fields (figure 22.7A). If attention to a restricted locus within a V4 receptive field causes a multiplicative scaling of the responses of selected neurons in earlier cortical stages, the limited distribution of attentional effects among the neurons contributing to the V4 cell would shift its receptive field center (figure 22.7B). Because receptive fields grow larger at successive levels of cortical processing, spatially selective attention would be expected to shift receptive field profiles in cortical stages beyond a site where it has its direct effect. A phenomenon of this sort could account for the effects observed by Moran and Desimone in V4 and inferotemporal cortex (1985), which they described as the receptive field contracting around the stimulus the animal was attending to. If attention acted at earlier levels to increase the gain of neurons representing one portion of a V4 receptive field while decreasing the gain of neurons representing another portion, the V4 receptive field could shift or contract.

Receptive field profiles may be special in this regard. Most other response properties have not been found to sharpen or broaden greatly in ascending the cortical hierarchy. If a V4 neuron receives inputs from two neurons with slightly offset receptive fields but the same orientation tuning (figure 22.7C), then selective enhancement of the responses of one of the input neurons would cause the orientation tuning curve of the V4 neuron to increase in amplitude but not in width (figure 22.7D).

Concluding comments

More data are needed before we understand the significance and scope of multiplicative scaling of sensory and behavioral signals in visual cerebral cortex. The current

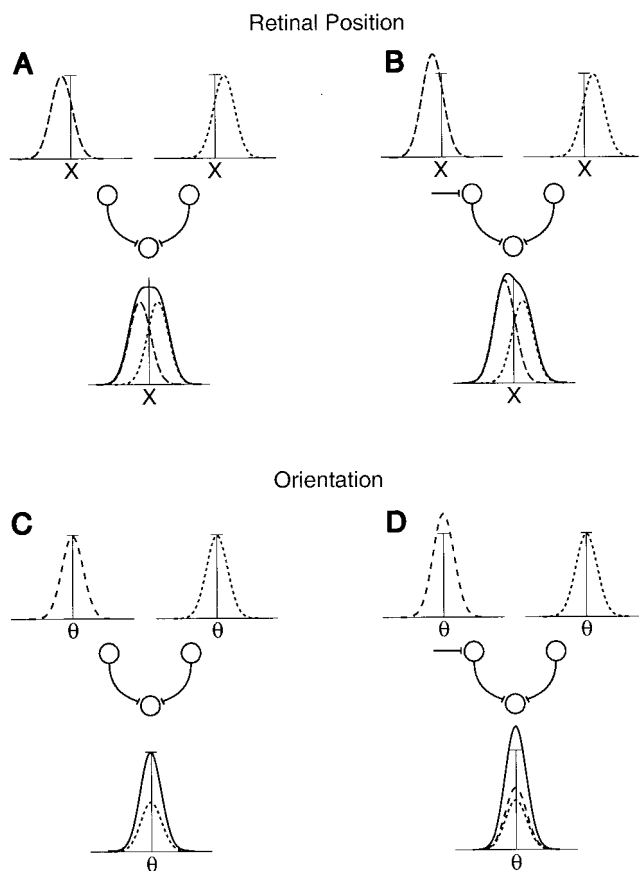

FIGURE 22.7 Different consequences of multiplicative scaling of tuning curves by attention. If attention acts only by multiplicative scaling of responses, it can nevertheless lead to changes in response properties that are not multiplicative scalings. This figure illustrates a hypothetical situation in which inputs from two neurons converge on a third. (A) Two neurons with slightly offset receptive fields converge on a third, which consequently has a receptive field (solid line) that is the sum of the receptive fields of the two input neurons (dashed and dotted lines). (B) If spatially selective attention acts to multiplicatively scale the responses of only one of the input neurons (dashed lines), the response profile of the third neuron (solid line) changes shape, such that the site of greatest sensitivity is offset. (C and D) No change in the response profile of the recipient neuron occurs if the input neurons share a common tuning curve, as might occur for orientation and other stimulus dimensions. If attention acts selectively on either of the input neurons, the third neuron will respond more strongly, but without a shift in its response profile.

experiments have examined just one stimulus attribute in one visual area using one behavioral task. It will be important to learn whether multiplicative scaling of responses by attention occurs for other stimulus attributes, cortical areas, and tasks. If attention does act primarily through scaling of response functions, it would suggest a simple accounting for the behavioral advantages conferred by attention. Attention may alter the cortical representation of the visual scene in a way that is equivalent

to increasing the contrast of those stimuli that currently have behavioral relevance. Whether the goal is detection or discrimination, behavioral performance should profit from this manipulation.

ACKNOWLEDGMENTS We thank Erik Cook, Ruth Anne Eatock, and Geoff Ghose for comments on preliminary versions of this chapter. The data for figure 22.1 were provided by Stefan Treue. 23 Response Synchronization: A Universal Coding Strategy for the Definition of Relations

WOLF SINGER

ABSTRACT It is proposed that the mammalian brain uses two complementary strategies for the representation of contents. First, items that are frequent, of low complexity, or of great behavioral relevance are represented by cells with specific response properties that acquire their selectivity through recombination of inputs in hierarchically organized feedforward architectures. Second, items that are infrequent, novel, of high complexity, or too diverse to be represented by individual neurons are encoded by dynamically associated assemblies of feature-tuned cells. Based on theoretical arguments and experimental findings, it is suggested that these assemblies are formed by rapid and transient synchronization of the responses of the associated neurons, coincident firing serving as the required signature of relatedness. It is concluded that this coding strategy is fully compatible both with the precision with which cortical networks handle temporally patterned activity and with the significance that nervous systems attribute to synchronized activity in the context of perception and learning. Thus, labeled line codes and assembly codes are complementary strategies, and so are rate codes and temporal codes.

Due to evolutionary selection, highly developed brains tend to employ optimized strategies for encoding and representing relevant environmental variables. However, because constraints often conflict, the implemented solutions are bound to be compromises. Optimal strategies differ for temporal and nontemporal features, processing speed is the rival of coding precision and flexibility, and all solutions are constrained both by the biophysical properties of neurons and the need to economize on neuron numbers. In this chapter we posit a coding strategy that exploits temporal synchrony of responses that defines relations among the responses of distributed neurons. As this coding strategy is essentially constrained by the precision with which neuronal networks can handle temporal patterns, we begin with the question of how well cortical networks can handle temporal patterns, then ask whether these can be used to

convey information in addition to that encoded in the amplitude of responses.

Temporal constraints

PRECISION Evidence indicates that neuronal networks can encode, transmit, and evaluate the temporal structure of stimuli with astounding precision. The highest degree of temporal resolution is probably reached in the specialized circuits of the auditory system, which exploit latency differences in the submillisecond range for sound localization (for review see Carr, 1993, and Middlebrooks, chapter 30 of this volume). Although signal transduction in the retina is slower than in the ear, the visual system, too, is capable of resolving temporal patterns with a precision in the millisecond range. Thus, timing differences in the millisecond range suffice for the identification of depth cues in rapidly moving patterns (Morgan and Castet, 1995), and stimulus onset asynchronies of <10 ms are readily exploited for perceptual grouping (Leonards, Singer, and Fahle, 1996). The visual system binds simultaneously appearing pattern elements and segregates them from elements presented with temporal offset (Leonards, Singer, and Fahle, 1996; Leonards and Singer, 1998; Alais, Blake, and Lee, 1998; Usher and Donnelly, 1998; but see Kiper, Gegenfurtner, and Movshon, 1996). Interestingly, the small latency differences that support sound localization or figure-ground segregation are not perceivable as temporal cues. There is thus a dissociation between the perceptibility of temporal stimulus features and their effect on early sensory processes.

Electrophysiological evidence confirms the ability of neuronal networks to transmit temporally modulated responses with a precision in the millisecond range over several processing stages. In the auditory cortex of owl monkeys species-specific calls evoke responses whose temporal modulation is so precise that intertrial variability of responses to the same call remains in the range of

WOLF SINGER Department of Neurophysiology, Max Planck Institute for Brain Research, Frankfurt, Germany

a few milliseconds (DeCharms and Merzenich, 1996). The visual system appears to operate with comparable precision. Cross-correlations between simultaneously recorded responses of retinal ganglion cells, relay neurons in the lateral geniculate, and cortical cells show that the oscillatory patterning of retinal responses is reliably transmitted to the cortex (Castelo-Branco, Neuenschwander, and Singer, 1998). Given the high frequency of the retinal oscillations (up to 100 Hz), this implies that the timing of discharges can be transmitted over several synaptic stages with a resolution in the millisecond range, at least when the discharges in parallel channels are precisely synchronized. The well synchronized cortical responses to flicker stimuli point in the same direction (Rager and Singer, 1998). This temporal fidelity of synaptic transmission is not confined to primary sensory pathways but holds, as well, for intracortical interactions. Cortical neurons can engage in oscillatory firing patterns in the γ -frequency range and synchronize their responses with millisecond precision over surprisingly large distances. Thus, cortical networks can handle temporally structured activity with low temporal dispersion (Engel et al., 1992, 1997; Singer and Gray, 1995; König, Engel, and Singer, 1996; see also Buracas et al., 1998, for the monkey).

These studies suggest several important conclusions. First, information about the temporal variables of stimuli can be encoded and transmitted over several processing stages with a precision in the millisecond range and, in specialized systems, in the submillisecond range. Second, there is a mechanism capable of evaluating the temporal covariation of responses—i.e., the degree of their synchronicity—with a resolution that exceeds the temporal resolution of conscious perception. Third, the mechanism that exploits temporal covariation of responses for perceptual grouping interprets simultaneous—i.e., synchronized—responses as related and segregates them from responses that follow a different time course.

Simulation studies indicate that such precision is readily obtained with neurons that operate within conventional time constants if transmission occurs in reciprocally coupled parallel channels—i.e., if a population coding strategy is used (Diesmann, Gewaltig, and Aertsen, 1996). In this case, neurons at the same processing level synchronize their discharges, whereupon these highly coherent pulse packets are conveyed with minimal dispersion across several synaptic stages, as postulated for synfire chains (Abeles, 1991). Population coding also compensates for low discharge rates and fluctuations in firing probability. As indicated in figure 23.1, precise timing information can be encoded in population responses without requiring drastic rate variations in individual

neurons if discharges in parallel channels are synchronized with sufficient precision and if the responses of the whole population are evaluated conjointly. Thus, when temporal patterns need to be transmitted with high precision, population coding is required and information about temporal variables is contained in the relative timing of spikes in parallel channels.

PROCESSING SPEED Another constraint assigning importance to the timing of discharges in distributed population responses is processing speed. Estimates based on reaction times, evoked potentials, and latencies of single-cell responses suggest that patterns of average complexity can be recognized within less than 100 ms. This leaves only a few tens of milliseconds per processing stage to perform the computations necessary for the selection and grouping of responses (Rolls and Tovee, 1994; Thorpe, Fize, and Marlot, 1996). If discharge rates vary between 0 and 100 Hz and interspike intervals follow a Poisson distribution, a neuron can emit maximally 3–4 spikes on average within the interval of interest, plus a few more spikes if it is bursting. Hence, the dynamic range exploitable for the transmission of rate-coded information about nontemporal stimulus features is very narrow. As proposed by Shadlen and Newsome (1998), this problem can also be overcome by population coding. However, if processing times are indeed in the range of tens of milliseconds, the population vectors need to be defined and read out at comparable time scales; thus it matters when, exactly, a cell participating in the population emits the few spikes that it can contribute within the available time window.

RATE CODING VERSUS TEMPORAL CODING Considerable disagreement attends the question of rate coding versus temporal coding. That is, do neurons in the central nervous system encode information solely by varying their discharge rate (Shadlen and Newsome, 1994, 1998) or do the temporal relations between the discharges in a population of neurons contain additional information (Softky and Koch, 1993; König, Engel, and Singer, 1996; Softky, 1995; Mainen and Sejnowski, 1995; Stevens and Zador, 1998; Buracas et al., 1998)? The arguments above suggest that this may be an ill-posed question because rate and temporal codes are complementary and convey information at different time scales. If a population of neurons is to signal the temporal features of a stimulus with a precision in the millisecond range, or if information about nontemporal features has to be encoded within short processing intervals, the amplitude of the population response must be modulated with time constants in the range of milliseconds. It must matter, then, when exactly and in which temporal relation the units comprising a

FIGURE 23.1 Signaling of precise timing by population coding and spike synchronization. The precise onset of a stimulus is signaled by a transient increase of spike density in the summed response of the population of four neurons (dotted line) without a noticeable rate change of the individual responses (traces 1–4). This is achieved by synchronization of the first spikes following stimulus onset. In this case, synchroniza-

tion is assumed to result from stimulus locking, i.e., from a transient increase in firing probability that occurs simultaneously in all four channels. The four neurons discharge with an average rate of 30 per second and the interval over which the population response is summed is assumed to be on the order of 15 ms.

population emit their action potentials because temporal dispersion of input or output spikes would change both the time course and the amplitude of the population response. However, once precise timing of discharges in a population response starts to matter, a fundamental criterion for rate codes is violated. Most, if not all, rate-coding concepts assume that the precise timing of spikes in a discharge sequence is irrelevant and that the frequency of spikes is the only significant parameter. The distinction between the two coding regimes becomes particularly problematic in the case of population coding. Here, the number of spikes in a time slice across the population response can be changed in two complementary ways—either by modulating discharge frequency of individual cells or by shifting the timing of spikes without altering average discharge rate. (A mechanism permitting the shifting of spikes is discussed below.) Thus, if a population of neurons is to transmit precise temporal information and/or to accomplish computations within a few tens of milliseconds, it is bound to operate in a regime where the relative timing of discharges is crucial. Why? Because computational results will be affected at least as much by temporal regrouping of discharges as by changing average rates. It

follows that, in population coding, information can, in principle, be encoded both by varying discharge rates and by changing the timing of individual spikes.

At all levels of sensory processing, there is a recurring need to define relations among the responses of simultaneously active neurons with high temporal resolution. We therefore propose that these binding functions are realized by temporal coordination of the discharges of distributed neuronal populations. According to Hebb (1949), such relations can be defined by a coordinated increase of the discharge rate of the selected neurons. This raises the saliency of the responses jointly and ensures that they are processed together at the next stage. Joint enhancement of the saliency of responses is thus equivalent to defining relations and binding selected responses for further joint processing. However, if such binding has to be accomplished rapidly and with high temporal resolution, the coherent rate fluctuations need to be so short that they cannot be adequately described in terms of rate changes. The reason for this is twofold. First, the patterns of coherent rate fluctuations—i.e., the binding patterns—can be changed without altering the average discharge rate of the involved neurons by regrouping of discharges.

Second, a definition of rates becomes meaningless if the intervals over which coherence is defined are shorter than the mean interspike intervals. We therefore advocate the hypothesis that the nervous system exploits the option to synchronize discharges in order to define relations among the responses of distributed neurons and to accomplish binding. Synchronizing the occurrence of spikes emitted by a population of neurons also raises the saliency of responses because coincident inputs drive the population of target cells at the next processing stage more effectively than temporally dispersed inputs (Alonso, Usrey, and Reid, 1996; Stevens and Zador, 1998). Thus, synchronization defines relations among distributed responses and assures binding in the same way that joint rate increases do, but does so with much higher temporal resolution.

TWO COMPLEMENTARY STRATEGIES FOR THE REPRESENTATION OF RELATIONS: SMART NEURONS AND ASSEMBLIES A major challenge for cognitive systems is the combinatorial complexity of the relations that need to be analyzed and represented. In the context of cognitive functions, combinatorial problems arise from the fact that perceptual objects consist of unique, often highly complex constellations of features that, in turn, represent specific relations among elementary sensory signals. Although the variety of basic feature dimensions that nervous systems exploit to classify perceptual objects is limited, the diversity of possible constellations is, for all practical purposes, unlimited. Thus, cognitive systems have to explore a huge combinatorial space when searching for the consistent relations among features that define a perceptual object. Combinatorial problems of similar nature have to be solved for the programming and execution of movements. Although the elementary components of motor acts—the movements of individual muscle fibers—are limited in number, the diversity of movements that can be composed by combining the elementary components in ever-changing constellations is, again, virtually infinite.

Encoding features and their constellations is the equivalent of encoding relations. One way to accomplish this is the recombination of signals via selective convergence of input connections in hierarchically structured feedforward architectures. In the primary visual cortex of mammals, for example, relations among the responses of collinearly aligned retinal ganglion cells are represented by having the output of these ganglion cells converge onto individual cortical neurons (Hubel and Wiesel, 1962; Chapman, Zahs, and Stryker, 1991; Jagadeesh, Wheat, and Ferster, 1993; Reid and Alonso, 1995). In this way, the feature “orientation” is extracted and represented. Iteration of this strategy in prestriate

cortical areas leads to increasingly smart neurons that encode more and more complex relations (Tanaka et al., 1991), including those characteristic for such real-world objects as faces (Gross, 1992). This strategy of representing features and their constellations by the tuned responses of individual cells (labeled line coding) is rapid and reliable because it can be realized by simple feedforward processing. However, if used as the only representational strategy, it requires astronomical numbers of neurons in order to cope with the virtually infinite diversity of possible feature conjunctions (Sejnowski, 1986; Engel et al., 1992). Moreover, it is not easy to see how such a strategy deals with the representation of novel objects at first encounter. These constraints apply not only for the representation of complex perceptual objects but also for the encoding of such elementary features as the precise position, shape, and orientation of a contour segment. Given the high spatial resolution with which these features can be distinguished, a very large number of neurons would be required if all possible conjunctions of these properties were encoded in a one-to-one relation by sharply tuned neurons.

A complementary strategy is needed—one that permits sharing of neurons for the representation of different contents. One such strategy is population coding, also known as “coarse coding.” Neurons are broadly tuned and signal with graded responses variations of features along several dimensions, e.g., orientation, location, and contrast of a contour border. Hence, a particular contour drives a large number of cells with overlapping preferences and the precise configuration of the stimulus can be assessed by interpolation from the population response. This coding strategy is common in sensory cortices, requires simple feedforward architectures, and engenders no decoding problem as long as the populations activated by simultaneously presented stimuli do not overlap too much. However, this strategy permits only representation of those features or feature conjunctions that are explicitly represented by the response properties of the cells comprising the population. A different coding strategy is required for the representation of feature constellations for which no specialized neurons exist. Such a strategy has been advocated by Hebb (1949), who proposed that a specific constellation of features should be represented by a dynamically associated assembly of cells which represents the respective feature conjunctions as a whole. The individual features associated in such assemblies can, in turn, be represented either by sharply tuned cells or, more economically, by population codes. This representational strategy also economizes on neuron numbers: The same cells can be bound successively into different assemblies. However, assembly codes differ from simple pop-

ulation codes in that they are based on active association of neurons into functionally coherent representations. Such active binding is necessary because conjunctions are no longer explicitly coded by the specific response properties of individual cells, but rather are defined by the association of cells into assemblies. Because this requires cooperative interactions among the members of an assembly, assembly codes cannot be implemented in architectures that possess only feedforward connections. Assembly formation requires, in addition, association connections that permit flexible binding of neuronal responses within and across processing levels. The fundamental difference between labeled line or population codes on the one hand and assembly codes on the other becomes particularly clear if one considers the processes required for the acquisition of new representations by learning. In the first case, the weight of feedforward connections must be changed to generate neurons that come to prefer new feature conjunctions. In the second case, the association connections need to be changed to permit preferential association of neurons that represent the new conjunction as an ensemble.

In sum, then, assembly coding requires that: (1) feature-selective neurons bind in variable constellations into different assemblies; (2) the rules of binding correspond to common Gestalt principles; (3) particular perceptual objects always activate the same assembly once learning has taken place and the association connections favoring stabilization of this assembly have been strengthened; and (4) the joint responses of cells comprising an assembly be distinguishable by subsequent processing stages as components of one coherent representation, thereby avoiding confusion with simultaneous responses of cells belonging to other assemblies and preventing the signaling of otherwise unrelated contents.

Numerous theoretical studies have addressed the question of how assemblies can self-organize on the basis of cooperative interactions within associative neuronal networks (for review, see Hebb, 1949; Braitenberg, 1978; Edelman, 1987; Palm, 1990; Gerstein and Gochin, 1992). Such studies have provided solutions compatible with the functional architecture of the cerebral cortex (for review, see Singer, 1995), but a critical question remains: How are the responses of cell assemblies tagged as related? An unambiguous signature of relatedness is crucial for assembly codes because the meaning of responses changes with context. Hence, false conjunctions are deleterious. Unfortunately, the risk of false conjunctions is constitutive in assembly coding: Assembly codes economize on neuron numbers only if the same cells can be bound into different assemblies at different times. Since complex scenes usually consist of spatially overlapping and contiguous objects, situations often arise when the

same group of neurons must be recruited simultaneously into different assemblies. As a matter of principle, then, assemblies that share common neurons but describe different objects cannot overlap in time. They have to be generated successively to avoid their merging. Processing speed is thus critically limited by the rate at which different assemblies can be formed and dissolved. At peripheral levels of processing where conjunctions are defined for many different, often spatially contiguous features, the alternation rate between assemblies coding for different conjunctions of features must be considerably faster than the rate at which different objects can be perceived and represented. The reason is that the results of the various grouping operations need to be interpreted jointly by higher processing stages for the evaluation of relations of higher order. Hence, the multiplexed results of low-level grouping must alternate fast enough to permit their association at higher processing stages even though they are transmitted as a sequence.

Similar superposition problems could also arise in population coding. If two contours are close or overlapping, there will always be a set of cells that respond to both contours even if these differ in certain features and ought to be processed. Segregating the respective populations spatially is no solution—it would require more neurons than implementing sharply tuned cells right away. The possibility should be considered, therefore, that under certain conditions population codes, too, might require disambiguation by temporal multiplexing.

THE SIGNATURE OF ASSEMBLIES The simplest way to define relations among the responses of neurons and to bind them together for joint processing is to raise the saliency of the selected responses, either by joint rate increases or by synchronization or both. And, given the constraints of processing speed, the time constants for the reconfiguration of assemblies should be in the order of tens of milliseconds or less. This implies that the saliency of the selected responses must be defined within intervals of just a few tens of milliseconds, and hence a temporal resolution in which coordination of spike timing is more important than modulation of average discharge rate. Thus, for short-lived assemblies, the appropriate signature of relatedness is the synchronization of discharges with a precision in the millisecond range. As with the signaling of rapid stimulus transients by synchronous population responses, synchronization has an additional effect—transmission of signals is accelerated and the temporal signature of the synchronized responses can be preserved across successive processing stages. This increases processing speed further while preserving the signature of assemblies during subsequent processing. Finally, as indicated in figure 23.2, cells can be bound successively

FIGURE 23.2 Disambiguation of temporally overlapping assemblies by synchronization of discharges in selected response segments. Despite the sustained and constant discharge rate (~ 30 Hz) of the ten depicted cells, the saliency of responses is transiently and repeatedly increased for three different, spatially overlapping assemblies (A, B, C) by synchronization of the discharges of the subpopulations of cells comprising the three assemblies. Note that the individual spike trains appear nonoscillatory while the spike density of the population response fluctuates periodically (lower continuous line). Note

also that cells 5 and 7 are shared by two and cell 3 is shared by all three assemblies. Because cell 3 contributes spikes to more assemblies than the others, its discharge frequency is slightly higher. In this case, the different assemblies are interleaved with a rate of 40 Hz and the integration interval for the evaluation of the population response is assumed to be around 10 ms. Faster multiplexing could be achieved by having all assemblies oscillate at 40 Hz and separating them by phase shifts. However, in this case integration time constants would have to be shorter.

into several different assemblies without overt modification of their average discharge rate if their discharges are appropriately grouped in time. This leaves the option to use sustained modifications of average rates in parallel for other functions. Thus, defining relations among distributed responses by synchronization has a number of advantages. It defines relations with high temporal precision, accelerates processing, facilitates transmission of signatures of relatedness across processing stages, and provides the option to use average discharge rate for the encoding of additional information.

Mechanisms for temporal grouping of responses

STIMULUS LOCKING VERSUS INTERNAL PATTERNING
In sensory systems, precise synchronization of discharges typically results from the locking of responses to temporally structured stimuli. As discussed, this externally induced synchronicity of discharges is interpreted as a signature of relatedness and supports perceptual grouping. Thus, synchronization of responses, if induced

by external stimuli, has exactly the binding function postulated above for the tagging of assemblies. How, then, does the nervous system achieve grouping and segregation of responses when stimuli lack a distinct temporal structure or when the temporal structure of stimuli conflicts with other, nontemporal grouping cues? Does the brain then use an entirely different strategy for the binding of responses, implementing different learning rules, or is there a way to use the synchronization of responses as a signature of relatedness for nontemporal stimulus properties as well?

Consider: (1) The responses of cortical neurons to moving stimuli often exhibit an oscillatory patterning that is not stimulus-locked (Gray and Singer, 1987); (2) these temporally structured discharges can become synchronized for neurons distributed both within (Gray and Singer, 1987, 1989) and across cortical areas (Gray et al., 1989; Engel, König, Kreiter, et al., 1991; Engel, König, and Singer, 1991; Engel, Kreiter, et al., 1991); (3) synchronization probability reflects common Gestalt criteria of perceptual grouping (Gray et al., 1989; Engel,

König, and Singer, 1991; Engel, Kreiter, et al., 1991; Kreiter and Singer, 1992, 1996; Freiwald, Kreiter, and Singer, 1995). In the light of these discoveries, we proposed that the cerebral cortex imposes a temporal microstructure on otherwise sustained responses, using this temporal patterning to express, through synchronization, the degree of relatedness of the responses.

In principle, temporal patterning and synchronization can be achieved in two ways; and, in fact, evidence suggests that both are exploited. First, cells could generate additional, precisely timed spikes as a result of a transient, well synchronized reduction of inhibition or an increase of excitatory drive. Second, spikes that would have occurred anyway could be shifted so that they coincide within the critical window. In the first case, the temporal patterning and synchronization may be associated with a measurable change in discharge rate; in the second case, it is not. In both cases, however, one would measure a transient increase in spike density within the interval where discharges are synchronized if one could record simultaneously from a sufficiently large number of cells and sum across the population. The time of occurrence of synchronized discharges is not locked to any external event when synchronization is caused by internal interactions. Thus, synchronized response segments cannot be detected by compiling histograms from the responses of individual neurons, even if synchronization is achieved by inserting additional spikes and hence is associated with a transient increase in discharge rate. The only way to detect internally generated synchrony is to record simultaneously from more than one unit, then perform correlation analysis.

Studies employing such multicell recordings offer growing evidence that the temporal patterning of responses and their synchronization by internal neuronal interactions are frequent phenomena observable in many cerebral structures (for recent reviews, see Singer and Gray, 1995; Singer et al., 1997). Moreover, these temporal patterns are often seen to have an oscillatory component which is best revealed by recording jointly the activity of several adjacent cells. The better detectability of oscillations in population responses has a two-fold explanation. First, individual cells tend to skip oscillation cycles in an irregular manner; second, oscillatory epochs are usually short and oscillation frequencies variable. This suggests that the periodicity of oscillatory population responses is often not apparent in the firing patterns of individual cells, even if their discharges are precisely phase-locked to the oscillatory activity of the population (figure 23.2).

If, like stimulus-locked synchronization, internally generated synchronization is to serve as a signature of relatedness, it must meet several criteria. First, its preci-

sion should be in the millisecond range to permit multiplexing of different assemblies at a rate fast enough to be compatible with known processing speed. Second, for the same reason, it must be possible to synchronize responses within a few tens of milliseconds. Third, one should find evidence that synchronized activity is more effective than nonsynchronized activity in driving cells in target structures, because precise synchronization can serve as a tag of relatedness only if it effectively enhances the saliency of the synchronized responses. Fourth, there should be a close correlation between the occurrence of these precise and rapidly changing synchronization patterns on the one hand and perceptual or motor processes on the other.

TEMPORAL CONSTRAINTS The postulate that internally generated synchronization should be as precise as externally induced synchronization is well supported by cross-correlation data. The widths of the correlation peaks at half-height are typically in the range of <10 ms (for review, see Singer et al., 1997). In particular, when the global EEG is in a desynchronized state, internally generated synchronization is often associated with an oscillatory patterning of the respective responses in the high β - or the γ -frequency range (from 20 to 60 Hz) (Munk et al., 1996; Herculano et al., in press). This reduces the probability of spurious correlations and enhances further the precision with which synchronized responses are distinguished from nonsynchronized responses.

The second postulate that internally generated synchronization must be established very rapidly (within a few tens of milliseconds) has received theoretical and experimental support recently. Simulations with spiking neurons reveal that networks of appropriately coupled units can indeed undergo very rapid transitions from uncorrelated to synchronized states (Hopfield and Hertz, 1995; Deppisch et al., 1993; Bauer and Pawelzik, 1993; Gerstner and Van Hemmen, 1993; Gerstner, 1996; Van Vreeswijk, Abbot, and Ermentrout, 1994). Rapid transitions from independent to synchronized firing are also observed in natural networks (Gray et al., 1992). In visual centers, it is not uncommon that neurons engage in synchronous activity, often with additional oscillatory patterning, at the very same time they increase their discharge rate in response to the light stimulus (Neuenschwander and Singer, 1996; Castelo-Branco, Neuenschwander, and Singer, 1998; Gray et al., 1992).

Recently, combined in vitro and in vivo experiments have suggested a new synchronization mechanism that operates extremely fast and could permit a rapid read-out of the grouping criteria that reside in the functional architecture of cortical connections. This mechanism exploits two properties—first, the ability of oscillating cells to delay

their output relative to incoming EPSPs and, second, the oscillatory patterning of ongoing cortical activity.

When the membrane potential of a cell undergoes an oscillatory modulation, EPSPs with an NMDA-receptor-mediated component do not necessarily evoke spikes at the time of occurrence but only when the cell reaches the peak of the next depolarizing cycle. The reason is that NMDA receptors still occupied by glutamate are reactivated by the removal of the voltage-dependent magnesium block (Volgushev, Chistiakova, and Singer, 1998). Thus, responses can be delayed considerably, whereby the maximum delay interval depends on oscillation frequency and can amount to almost the duration of one cycle. With such a mechanism, responses to temporally dispersed EPSPs can be synchronized within less than an oscillation cycle. This option appears to be exploited for the rapid synchronization of responses. Response latencies of cortical neurons fluctuate in the range of about 20 ms for identical, repeatedly presented stimuli; however, recent correlation studies indicate that these fluctuations can be correlated for responses of neurons located in different columns (Fries, Roelfsema, Engel, et al., 1997; Fries, Roelfsema, Singer, et al., 1997). The data suggest that this rapid adjustment of response latencies is due to coherent oscillations of the membrane potential of the respective neurons and hence is, in all likelihood, based on the delay mechanism identified in the slice experiments.

The ongoing fluctuations of cortical activity are not random. Rather—as shown with a different approach by Arieli and colleagues (1996)—they exhibit specific spatiotemporal patterns that are likely to reflect the functional architecture of intracortical connections. These, in turn, are known to preferentially link columns coding for related features that tend to be grouped perceptually (Gilbert and Wiesel, 1989; Ts'o and Gilbert, 1988; Malach et al., 1993; Schmidt et al., 1997). Physiological data suggest that these corticocortical connections contribute to the synchronization of spatially segregated groups of neurons (Engel, König, Kreiter, et al., 1991; Löwel and Singer, 1992; König et al., 1993; Nowak et al., 1995). It is conceivable, then, that the grouping criteria residing in the functional architecture of the intracortical association connections are continuously translated into specific spatiotemporal patterns of membrane potential fluctuations, and these in turn serve the rapid temporal coordination of responses to incoming sensory signals. If the pattern of these fluctuations is also modified by top-down influences from higher cortical areas and by immediately preceding changes of sensory input, these dynamic patterns would be equivalent with the system's updated expectancy against which incoming activity is matched. One of the effects of matching these predic-

tions with incoming signals is a rapid temporal regrouping of output activity (figure 23.3).

Obviously, the grouping of responses by internal adjustment of temporal patterns should not override grouping by stimulus-locking to preserve temporal grouping cues inherent in dynamic scenes. As discussed elsewhere, a solution to this problem is parallel processing of signals about temporal and nontemporal stimulus features (Leonards and Singer, 1997, 1998). In this case, responses signaling the precise temporal structure of stimuli could be exempted from latency adjustments while responses signaling nontemporal features could be subject to internal temporal patterning. This scenario is supported by psychophysical evidence. Experiments on texture segregation suggest, first, that the grouping mechanism exploiting the temporal signature of stimuli relies mainly on the transient responses of the magnocellular system (Leonards and Singer, 1998) and, second, that these temporally precise signals are used to make inferences on the temporal structure of stimuli activating preferentially the parvocellular pathways (Leonards and Singer, 1997). Third, these experiments suggest that the grouping mechanisms relying on external timing and internal patterning, respectively, cooperate synergistically if both temporal and nontemporal cues define the same figure while they compete with one another, provided patterns are presented in which temporal and nontemporal features define different, spatially overlapping figures. Most importantly, however, conflicting temporal cues do not interfere with the binding of nontemporal features if these temporal cues do not define a figure (Leonards, Singer, and Fahle, 1996). Thus, temporal and nontemporal grouping cues appear to be processed in parallel but not independently—a finding consistent with the anatomical organization of the magno- and parvocellular processing streams (for review, see Maunsell, 1995).

RELATIONS BETWEEN RESPONSE SYNCHRONIZATION, COGNITION, AND MOTOR PERFORMANCE One line of support for a functional role of the oscillatory patterning of responses in the β - and γ -frequency range and for precise synchronization comes from the finding that these phenomena are particularly well expressed when the brain is in an activated state, i.e., when the EEG is desynchronized and exhibits high power in the β - and γ -frequency range (figure 23.4; Munk et al., 1996). Such EEG patterns are characteristic for the aroused and attentive as well as the dreaming brain (see Hobson, 1988) and hence for states in which sensory representations can be activated. Conversely, both the oscillatory patterning of responses in the γ -frequency range (Madler et al., 1991) and the precise synchronization disappear

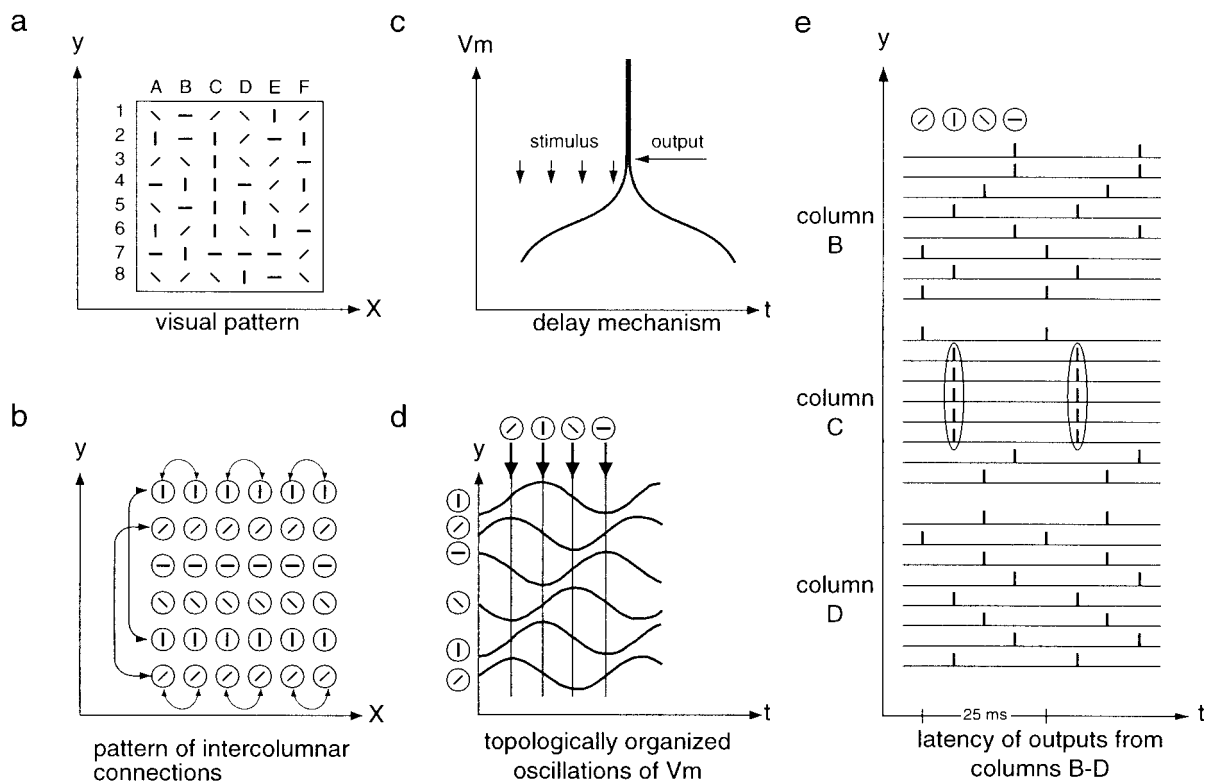

FIGURE 23.3 A putative mechanism for the rapid conversion of perceptual grouping rules into a temporal code. (a) Due to the grouping criterion of collinearity, the vertical bars in column C and the horizontal bars in row 7 are bound together and are perceived as the letter L. (b) In agreement with anatomy it is assumed that cortical columns preferring similar orientations are coupled preferentially. (c) Schematic representation of the mechanism that delays the output of a cell with oscillating membrane potential until the depolarizing peak of the respective next oscillation cycle is reached (horizontal arrow) irrespective of when the EPSPs are generated (vertical arrows). (d) Due to preferential coupling, cells preferring the same ori-

entation are assumed to exhibit coherent oscillations of their membrane potential, but oscillations of cells with different preferences are assumed to be phase-shifted. Thus, cells sharing the same preferences will emit synchronized responses and cells with differing preferences temporally offset responses. (e) Latency distribution of discharges of cells responding to pattern elements in columns B, C, and D of panel a. Latencies correspond to the phase-shifted oscillations of cells preferring different orientations as depicted in d. Note that the cells responding to the collinear bars in column C (panel a) discharge synchronously, which allows for rapid binding of the respective responses.

when anesthesia is deepened and/or if the animal is in slow wave sleep and the EEG exhibits prominent δ activity. In this case, synchronization collapses long before the amplitudes of neuronal responses get attenuated (unpublished observations). Numerous observations, both in animal and human subjects, point in the same direction. For example, synchronous oscillations in the γ -frequency range and their synchronization become more prominent during states of focused attention (Roelfsema et al., 1996; Murthy and Fetz, 1996a,b; De Oliveira, Thiele, and Hoffmann, 1997) or when subjects are engaged in visual discrimination tasks that put strong demands on feature binding or short-term memory functions (Tallon-Baudry et al., 1995, 1996, 1997).

Direct relations between response synchronization and perception have been found in cats who suffered from strabismic amblyopia. Surprisingly, the responses of indi-

vidual neurons in the cat primary visual cortex fail to reflect the deficits associated with amblyopic vision (see Roelfsema et al., 1994, for references). The only significant correlate of amblyopia was the drastically reduced ability of neurons driven by the amblyopic eye to synchronize their responses. This accounts well for the perceptual disturbances: Impaired synchronization reduces the saliency of responses and therefore can explain the suppression of signals from the amblyopic eye. Moreover, deficiencies in the synchronizing mechanism are bound to impair the disambiguation of population codes, which accounts for the most characteristic disturbances in amblyopia—reduced visual acuity and the crowding phenomenon.

Another close correlation between response synchronization and perception has been found in experiments on binocular rivalry in strabismic animals (Fries,

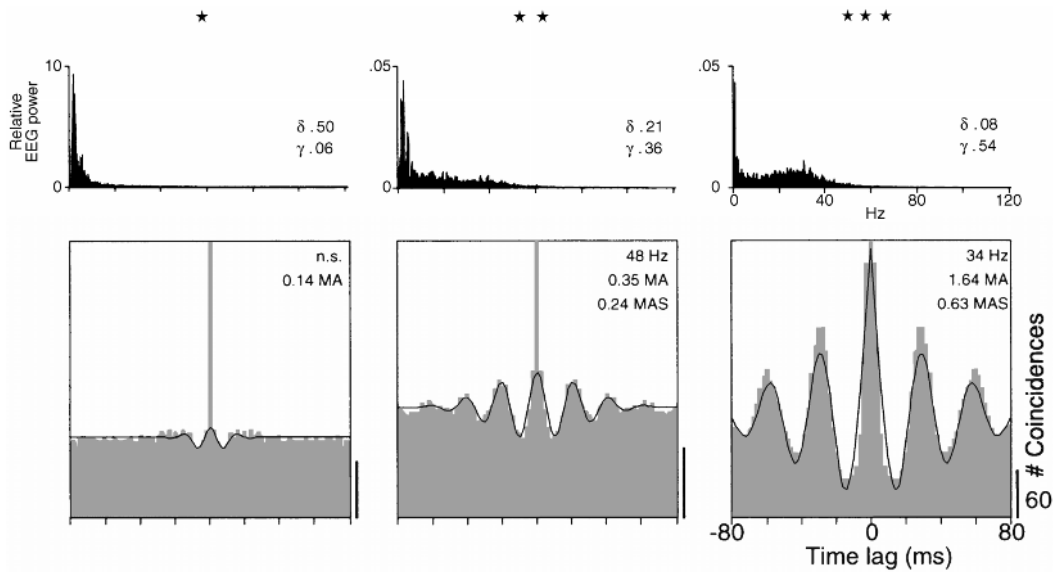

FIGURE 23.4 State dependence of response synchronization. Upper row: Power distribution in the EEG recorded during three episodes from an anesthetized cat. Lower row: Averaged cross-correlograms of multiunit responses evoked by a drifting grating and recorded from two different sites in A17 during corresponding episodes. Note that the synchronization of the responses and the oscillatory modulation in the γ -frequency range

increase with increasing γ -activity in the EEG. Inserts in the power spectra give the relative power in the δ - and γ -frequency range. Inserts in the cross-correlograms give the oscillation frequency (in hertz), the relative modulation amplitude of the center peak (MA), and of the first side peak (MAS). (From Herculano et al., in press.)

Roelfsema, Engel, et al., 1997). Due to experience-dependent modifications of processing circuitry (Wiesel and Hubel, 1965; Löwel and Singer, 1992), perception in nonamblyopic strabismic subjects always alternates between the two eyes. We have exploited this phenomenon of rivalry to investigate how neuronal responses that are selected and perceived differ from those that are suppressed and excluded from supporting perception (figure 23.5). The outcome of these experiments was surprising. The responses of neurons in areas 17 and 18 were not attenuated during epochs in which they were excluded from controlling eye movements and supporting perception. A close and highly significant correlation existed, however, between changes in the strength of response synchronization and the outcome of rivalry. Cells mediating responses of the eye that won in interocular competition increased the synchronicity of their responses upon presentation of the rivalrous stimulus to the losing eye, while the reverse was true for cells driven by the eye that became suppressed. Thus, selection of responses for further processing appeared to be achieved by modulating the degree of synchronization rather than the amplitude of responses.

These results are direct support for the hypothesis that precise temporal relations between the discharges of spatially distributed neurons matter in cortical processing and that synchronization may be exploited to jointly raise the saliency of the responses selected for further processing. The important point here is that this selec-

tion is apparently achieved without enhancing the average discharge rate of the selected responses or inhibiting the nonselected responses.

The fact that both in amblyopia and binocular rivalry only well synchronized activity supports perception agrees with the notion that well synchronized responses are more salient and have a stronger impact on cells at subsequent processing stages than poorly synchronized responses. Further support comes from a recent multi-electrode study on corticotectal interactions in the cat (Brecht, Singer, and Engel, 1998). Tectal cells get synchronized to responses of cells in visual cortical areas if the respective cell groups are activated by the same contour, suggesting synchronization of tectal responses by corticotectal projections. This synchronizing effect is strongly enhanced when the responses of cortical cells are themselves well synchronized among each other, irrespective of whether the relevant cortical cells are located within a single cortical area or are distributed across different areas, in this case between areas 17, 18, and area PMLS (figure 23.6). This indicates that cortical cells are more effective in driving common tectal target cells when their responses are synchronized than when they fire independently. Again, these changes in functional coupling cannot be explained by rate changes. When neurons synchronize their responses, the discharge rate usually does not increase; rather, average discharge rates either remain unchanged or decrease (Herculano et al., in press).

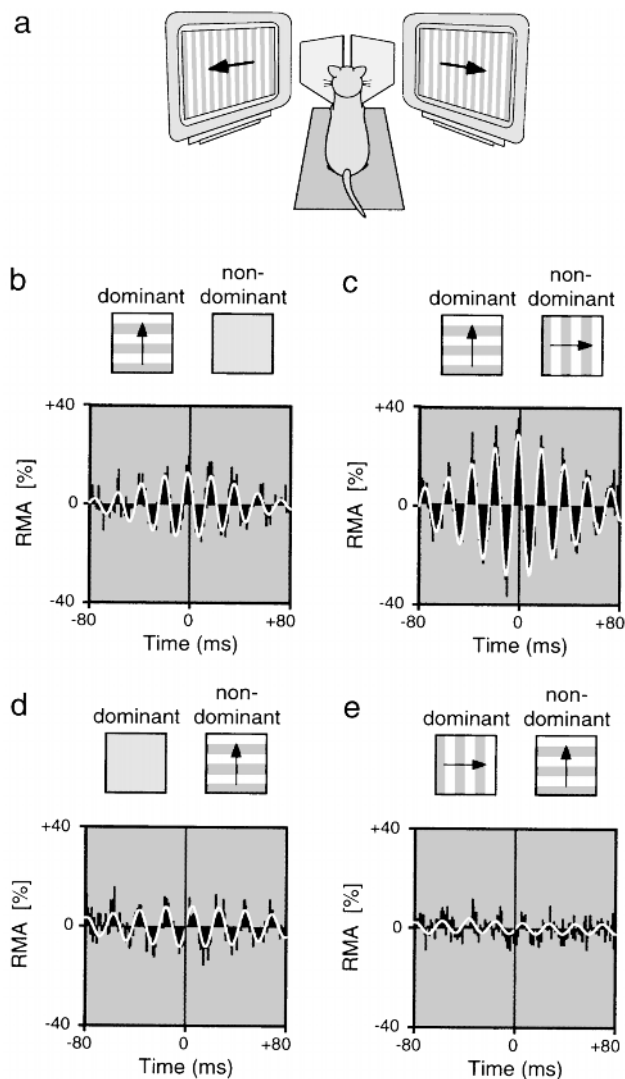

FIGURE 23.5 Neuronal synchronization under conditions of binocular rivalry. (a) Using two mirrors, different patterns were presented to the two eyes of strabismic cats. (b–e) Normalized cross-correlograms for two pairs of recording sites activated by the eye that won (b and c) and lost (d and e) in interocular competition. Insets above the correlograms indicate stimulation conditions. Under monocular stimulation (b), cells driven by the winning eye show a significant correlation which is enhanced after introduction of the rivalrous stimulus to the other eye (c). The reverse is the case for cells driven by the losing eye (compare conditions d and e). The white continuous line superimposed on the correlograms represents a damped cosine function fitted to the data. The relative modulation amplitude (RMA) of the center peak in the correlogram, is computed as the ratio of peak amplitude over offset of correlogram modulation. This measure reflects the strength of synchrony. (Modified from Fries, Roelfsema, Engel, et al., 1997.)

Further indications for a functional role of precise timing relations between the discharges of distributed neurons have recently been obtained with multielectrode recordings from the motor and prefrontal cortex of monkeys performing a visually cued reaching task. In a study

FIGURE 23.6 Dependence of corticotectal synchronization on intracortical synchronization within (left plots) and across (right plots) cortical areas. Left: Percentage of significant corticotectal correlations when cortical cells recorded from two sites in the same cortical area synchronize (shaded column) or do not synchronize (black column) their responses. Right: Percentage of corticotectal interactions between A17 and the tectum when area 17 cells synchronize (shaded column) or do not synchronize (black column) their responses with those of cells in the lateral suprasylvian sulcus. (From Brecht, Singer, and Engel, 1998.)

by Riehle and colleagues (1997), the monkeys' anticipation of cued motor responses was deducible from the occurrence of supernumerary coincidences among discharges of neurons in primary motor cortex, while no such inferences could be drawn from rate fluctuations of individual neurons. Other studies (Vaadia et al., 1995; Prut et al., 1998) report a similar relation between a precise temporal coordination of the discharges of simultaneously recorded neurons and cued motor responses in the prefrontal cortex. Finally, Hatsopoulos, Ojakangas, and Donoghue found transient and highly precise synchronization among cells in motor cortex that were related to the direction of motion and the extent to which a particular stimulus–response association had been practiced and learned (Hatsopoulos, Ojakangas, and Donoghue, 1997; Ojakangas, Hatsopoulos, and Donoghue, 1997; Donoghue et al., 1998). Complementary support for a functional role of precise spike timing comes from studies of the insect olfactory system. As in the mammalian olfactory bulb (Freeman and Skarda, 1985), odors evoke oscillatory population responses in the antennal lobes and hence synchronized volleys of spikes in parallel channels. Interestingly, information about the composition of a particular odor is encoded both in the pattern of rate fluctuations in parallel channels and in the distribution of coincident spikes (Macleod and Laurent, 1996; Wehr and Laurent, 1996; Stopfer et al., 1997). When the oscillatory patterning and the resulting synchronization are disrupted by pharmacological manipulations without

modification of the spatiotemporal pattern of rate fluctuations, simple, noncomposite odors could still be discriminated while complex, composite odors were confounded (Macleod and Laurent, 1996; Wehr and Laurent, 1996; Stopfer et al., 1997).

Conclusions

Taken together, the data and arguments expounded in this chapter support the notion that neuronal networks are capable of evaluating with a precision in the millisecond range the temporal relations among the discharges of neuronal populations and that they exploit this ability for two purposes: First, for the precise signaling of temporal features across processing stages; and second, for the definition of relations among distributed responses with high temporal resolution. Such a relation defining or binding mechanism is indispensable in ensemble coding because this representational strategy requires flexible and rapid binding of distributed responses in ever-changing constellations. Assembly coding, in turn, appears necessary in order to cope with the representation of the astronomical number of possible relations among features describing real-world objects. It appears, then, as if the cerebral cortex applies two complementary coding strategies: First, an explicit representation of features and their conjunctions in the tuned responses of individual, specialized neurons or populations of such neurons; and second, an implicit representation of conjunctions of such explicitly coded contents in dynamically associated assemblies. The first strategy seems to be applied for the representation of a limited set of features and some of their conjunctions. In all likelihood, this strategy is reserved for items that occur very frequently and/or are of particular behavioral importance, such as faces and expressions. The second strategy seems to be reserved for the representation of all those items for which an explicit representation cannot be realized, either because the explicit representation would require too many neurons or because the contents to be represented are too infrequent to warrant the implementation of specialized neurons. Also, the second strategy seems to be the only way to represent novel contents as there cannot be specialized neurons for them at first encounter. However, if novel items acquire high behavioral significance, as is the case for stimuli used in experiments with trained monkeys, it appears that these do become represented explicitly by specialized neurons (Miyashita, 1993; Logothetis, Pauls, and Poggio, 1995). In conclusion, then, there is no incompatibility between the strategy to encode contents by rate-modulated smart neurons on the one hand and by temporally defined assemblies on the other. Rather, the two regimes are coexistent and ideally complement one another.

24 Lightness Perception and Lightness Illusions

EDWARD H. ADELSON

ABSTRACT A gray surface in sunlight may have much higher luminance than it has in the shade, but it still looks gray. To achieve the task of “lightness constancy,” the visual system must discount the illumination and other viewing conditions and estimate the reflectance. Many different physical situations, such as shadows, filters, or haze, can be combined to form a single, simple mapping from luminance to reflectance. The net effect of the viewing conditions, including additive and multiplicative effects, may be termed an “atmosphere.” An “atmospheric transfer function” maps reflectance into luminance. To correctly estimate lightness, a visual system must determine a “lightness transfer function” that performs the inverse. Human lightness computation is imperfect, but performs well in most natural situations. Lightness illusions can reveal the inner workings of the estimation process, which may involve low-level, mid-level, and high-level mechanisms. Mid-level mechanisms, involving contours, junctions, and grouping, appear to be critical in explaining many lightness phenomena.

Every light is a shade, compared to the higher lights, 'til you come to the sun; and every shade is a light, compared to the deeper shades, 'til you come to the night.

—John Ruskin (1879)

The amount of light coming to the eye from an object depends on the amount of light striking the surface and on the proportion of light that is reflected. If a visual system made just a single measurement of luminance, acting as a photometer, there would be no way to distinguish a white surface in dim light from a black surface in bright light. Yet humans can usually do just that. This skill is known as *lightness constancy*.

The constancies are central to perception. An organism needs to know about meaningful world-properties—color, size, shape, etc. These properties are not explicitly available in the retinal image, but are extracted by visual processing. The gray shade of a surface is one such property. To extract it, luminance information must be combined across space. In figure 24.1, for example, we see the well known *simultaneous contrast* effect, which demonstrates a spatial interaction in lightness percep-

tion. The two smaller squares are the same shade of gray, but the square in the dark surround appears lighter than the square in the light surround. This is, of course, an illusion, which may be viewed as a quirky failure of perception. But such illusions are also revealing, allowing us to examine the inner workings of a system that functions remarkably well. Here we consider how lightness illusions can inform us about lightness perception.

Levels of processing

The visual system processes information at many levels of sophistication. At the retina, there is *low-level vision*, including light adaptation and the center-surround receptive fields of ganglion cells. At the other extreme is *high-level vision*, which includes cognitive processes that incorporate knowledge about objects, materials, and scenes. In between there is *mid-level vision*. Mid-level vision is simply an ill-defined region between low and high. The representations and the processing in the middle stages are commonly thought to involve surfaces, contours, grouping, and so on. Lightness perception seems to involve all three levels of processing.

The low-level approach to lightness is associated with Ewald Hering. He considered adaptation and local interactions, at a physiological level, as the crucial mechanisms. This approach has long enjoyed popularity because it offers an attractive connection between physiology and psychophysics. Figure 24.2a shows the receptive field of an idealized center-surround cell. The cell exhibits lateral inhibition: light in the center is excitatory while light in the surround is inhibitory. A cross-section of the receptive field is shown in figure 24.2b. This cell performs a local comparison between a given luminance and the neighboring luminances, and thus offers machinery that can help explain the simultaneous contrast (SC) illusion. This idea was formalized by Ernst Mach, who proposed a Laplacian derivative operator as the mechanism.

One of Mach's inspirations was an illusion now known as the Mach band. When a spatial ramp in luminance abruptly changes slope, an illusory light or dark

EDWARD H. ADELSON Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, Mass.

FIGURE 24.1 The simultaneous contrast effect.

FIGURE 24.2 Center-surround inhibition.

FIGURE 24.3 An illusion by Vasarely (a) and a bandpass filtered version (b).

band appears. A variant of the Mach band has been used by the op artist Vasarely, as shown in figure 24.3a. The image consists of a set of nested squares. Each square is a constant luminance. The pattern gives the illusion of a glowing X along the diagonals, even though the corners of the squares are no brighter than the straight parts. When a center-surround filter is run over this pattern (i.e., is convolved with it), it produces the image shown in figure 24.3b. The filter output makes the bright diagonals explicit.

A center-surround filter cannot explain a percept by itself: Perception involves the whole brain. However, center-surround responses can go a long way toward explaining certain illusions.

Derivative operators respond especially well to sharp intensity transitions such as edges. The importance of

FIGURE 24.4 One version of the Craik-O'Brien-Cornsweet effect.

edges, and the lesser importance of slow gradients, is indicated by the *Craik-O'Brien-Cornsweet effect* (COCE) named after its several discoverers. Figure 24.4 shows one of several COCE variants. The figure appears to contain a dark square next to a light square. Actually, the two squares are ramps, and they are identical, as shown by the luminance profile underneath (the dashed lines show constant luminances). The response of a center-surround cell to this pattern will be almost the same as its response to a true step edge—a big response at the edge and a small response elsewhere. While this doesn't explain why the image looks as it does, it may help explain why one image looks similar to the other (Cornsweet, 1970).

Center-surround processing is presumably in place for a good reason. Land and McCann (1971) developed a model they called Retinex, which placed the processing in a meaningful computational context.

Land and McCann began by considering the nature of scenes and images. They argued that reflectance tends to be constant across space except for abrupt changes at the transitions between objects or pigments. Thus a reflectance change shows itself as a step edge in an image, while illuminance changes gradually over space. By this argument one can separate reflectance change from illuminance change by taking spatial derivatives: High derivatives are due to reflectance and low ones to illuminance.

The Retinex model applies a derivative operator to the image, and thresholds the output to remove illuminance variation. The algorithm then reintegrates edge information over space to reconstruct the reflectance image.

The Retinex model works well for stimuli that satisfy its assumptions, including the Craik-O'Brien-Cornsweet

display and the “mondrians” (which roughly resemble paintings by the artist Piet Mondriaan) that Land and McCann used. A mondrian is an array of randomly colored, randomly placed rectangles covering a plane surface, and illuminated nonuniformly.

The real world is more complex than the mondrian world, of course, and the Retinex model has its limits. In its original form, it cannot handle the configural effects to be described later in this chapter. However, the Land–McCann research program articulated some important principles. Vision is possible only because there are constraints in the world; i.e., images are not formed by arbitrary random processes. To function in this world, the visual system must exploit the ecology of images—it must “know” the likelihood of various things in the world, as well as the likelihood that a given image-property could be caused by one or another world-property. This world-knowledge may be hardwired or learned, and may manifest itself at various levels of processing.

Limits on low-level processes

The high-level approach is historically associated with Hermann von Helmholtz, who argued that perception is the product of *unconscious inference*. His dictum was this: What we perceive is our visual system’s best guess as to what is in the world. The guess is based on the raw image data plus our prior experience. In the Helmholtz view, lightness constancy is achieved by inferring, and discounting, the illuminant. From this standpoint the details of low-level processing are not the issue. A lightness judgment involves the workings of the whole visual system, and that system is designed to interpret natural scenes. Simultaneous contrast and other illusions are the by-products of such processing.

Hochberg and Beck (1954) and Gilchrist (1977) showed that 3D cues could greatly change the lightness perception in a scene, even when the retinal image remains essentially unchanged, in accord with Helmholtz’s approach.

The importance of scene interpretation is also shown by a recent variant on the Craik–O’Brien–Cornsweet effect devised by Knill and Kersten (1991). In figure 24.5a, one sees two identical cylinders. In figure 24.5b one sees a brick painted with two shades of paint. Embedded within each image is a COCE pattern in the vertical direction. The two ramps are interpreted as shading in figure 24.5a, but as paint in figure 24.5b.

The Gestalt approach

The Gestalt psychologists approached lightness perception, and perception generally, in a different manner

FIGURE 24.5 Knill and Kersten’s illusion. Both figures contain the same COCE ramps, but the interpretations are quite different.

from the Hering or Helmholtz schools. They emphasized the importance of perceptual organization, much of it based on mechanisms that might be characterized as midlevel. The key concepts include grouping, belongingness, good continuation, proximity, and so on.

Koffka offered an example of how simultaneous contrast can be manipulated by changing spatial configuration. The ring in figure 24.6a appears almost uniform in color. When the stimulus is split in two, as shown in figure 24.6b, the two half-rings appear to be different shades of gray. The two halves now have separate identities, and each is perceived within its own context.

A novel variant that involves transparency is shown in figure 24.6c. The left and right half-blocks are slid vertically, and the new configuration leads to a very different perceptual organization and a strong lightness illusion. We will return to this stimulus in our later discussion.

Some terminology

Having outlined some basic phenomena, we now return to the basic problems. First, we clarify some terminology (more complete definitions can be found in books on photometry and colorimetry):

Luminance is the amount of visible light that comes to the eye from a surface.

Illuminance is the amount of light incident on a surface.

Reflectance is the proportion of incident light that is reflected from a surface.

Reflectance, also called *albedo*, varies from 0 to 1 or, equivalently, from 0% to 100% where 0% is ideal black

FIGURE 24.6 Variants on the Koffka ring. (a) The ring appears almost uniform. (b) When split, the two half-rings appear distinctly different. (c) When shifted, the two half-rings appear quite different.

and 100% is ideal white. In practice, typical black paint is about 5% and typical white paint about 85%. (To keep things simple, we consider only ideal matte surfaces, for which a single reflectance value offers a complete description.)

Luminance, illuminance, and reflectance are physical quantities that can be measured by physical devices. There are also two subjective variables that must be discussed:

Lightness is the perceived reflectance of a surface. It represents the visual system's attempt to extract reflectance based on the luminances in the scene.

Brightness is the perceived intensity of light coming from the image itself, rather than any property of the portrayed scene. Brightness is sometimes defined as perceived luminance.

These terms may be understood by reference to figure 24.7. The block is made of a 2×2 set of cubes, each colored either light or dark gray. We call this the “checker-block.” Illumination comes from an oblique angle, lighting different faces differently. The luminance image can be considered to be the product of two other images—the reflectance image and the illuminance image. These underlying images are termed *intrinsic images* in machine vision (Barrow and Tenenbaum, 1978). Intrinsic image decompositions have been proposed for understanding lightness perception (Arend, 1994; Adelson and Pentland, 1996).

Patches p and q have the same reflectance, but different luminances. Patches q and r have different reflectances and different luminances; they share the same illuminance.

FIGURE 24.7 The “checker-block” and its analysis into two intrinsic images.

Patches p and q appear to be painted with the same gray, and thus they have the same lightness. However, it is clear that p has more luminance than q in the image, and so the patches differ in brightness. Patches p and r differ in both lightness and brightness, despite having the same luminances.

Faces p and q appear to be painted with the same gray, and thus they have the same lightness. However, it is clear that p has more luminance than q in the image, and so the patches differ in brightness. Patches p and r differ in both lightness and brightness, despite having the same luminances.

The problem of lightness constancy

From a physical point of view, the problem of lightness constancy is as follows. An illuminance image, $E(x,y)$, and a reflectance image, $R(x,y)$, are multiplied to produce a luminance image, $L(x,y)$:

$$L(x,y) = E(x,y)R(x,y)$$

An observer is given L at each pixel and attempts to determine the two numbers, E and R , that were multiplied to make it. Unfortunately, unmultiplying two numbers is impossible. If $E(x,y)$ and $R(x,y)$ are arbitrary functions, then for any $E(x,y)$ there exists an $R(x,y)$ that produces the observed image. The problem appears impossible, but humans do it pretty well. This must mean that illuminance and reflectance images are not arbitrary functions. They are constrained by statistical properties of the world, as proposed by Land and McCann.

Note that Land and McCann's constraints fail when applied to the checkerblock image. Figure 24.8a shows

two light–dark edges. They are exactly the same in the image, and any local edge detector or filter will respond to them in the same way. Retinex will classify both as reflectance steps. Yet they have very different meanings. One is caused by illuminance (due to a change in surface normal); the other is caused by reflectance.

To interpret the edges, the visual system must consider them in a larger context. One good source of information is the junctions, where two or more contours come together. As shown in figure 24.8b, X, Y, L, T, and ψ are some of the simple junction types. The configuration of a junction, as well as the gray levels forming the junction, can offer cues about the shading and reflectance of a surface.

Particularly strong constraints are imposed by a ψ -junction like the one in figure 24.8b. The vertical spine appears to be a dihedral with different illuminance on the two sides. The angled arms appear to represent a reflectance edge that crosses the dihedral. The ratios of the gray levels, and the angles of the arms, are consistent with this interpretation.

The influence of a ψ -junction can propagate along the contours that meet at the ψ . A single light–dark edge, ambiguous by itself, can be pushed toward a particular interpretation by adjoining ψ 's (Sinha and Adelson, 1993).

In figure 24.9, the dashed rectangle encloses a set of horizontal light and dark stripes. If we consider only the

region within the dashed rectangle, we cannot determine the physical sources of the stripes. However, if we cover the right side of the figure and view the left side, it appears that the stripes are due to paint. If we cover the left side and view the right, it appears that the stripes are due to different lighting on the stair steps. If we view both sides, the percept flip-flops according to where we look.

The ψ -junctions seem to be in control here. If we follow a stripe to the left, it connects to a ψ with a vertical spine and becomes an arm of that ψ . The junction configuration, together with the junction gray levels, suggests that the stripe is due to reflectance. When the same strip is followed to the right, it joins a ψ with a horizontal spine. Again, the configuration and gray levels suggest that illuminance is the cause.

Configurations involving ψ 's can modulate brightness illusions. Figure 24.10 shows a stimulus we call the *corrugated plaid* (Adelson, 1993). In figure 24.10a the two marked patches are the same shade of gray. The upper patch appears slightly darker. Figure 24.10b shows another array of gray patches in which the same gray levels are at the same positions as in figure 24.10a; i.e., the raster sequence of grays is the same. Only the geometry has been changed, parallelograms having been substituted for squares and vice versa. The illusion is much enhanced, the upper patch appearing much darker than the lower one. In the laboratory the apparent luminance difference is increased threefold.

A low-level filtering mechanism, or a mechanism based on local edge interactions, cannot explain the change in the illusion. We proposed (Adelson, 1993) a Helmholtzian explanation based on intrinsic images: The change in ψ -junctions causes a change in the perception of 3D surface orientation and shading. In figure 24.10a the two test patches appear to be in the

FIGURE 24.8 (a) The local ambiguity of edges. (b) A variety of junctions.

FIGURE 24.9 The impossible steps. On the left, the horizontal stripes appear to be due to paint; on the right, they appear to be due to shading.

FIGURE 24.10 Variations on the corrugated plaid. (a) The two patches appear nearly the same. (b) The patches appear quite different. (c) The patches appear quite different, but there is no plausible shaded model. (d) Possible grouping induced by junctions.

same illumination, but in figure 24.10b they are differently illuminated. A brightly lit patch of dark gray looks quite different from a dimly lit patch of light gray. This lightness computation could have a strong influence on brightness judgments.

Thus a 3D shaded model can help explain the phenomenon. But is it necessary? Todorovic (1997) has de-

vised a variant, shown in figure 24.10c, that suggests not. The figure was made by mirror-reversing the bottom two rows. For many observers the illusion remains nearly as strong as in figure 24.10b. However, there is no reasonable interpretation in terms of a 3D shaded model. The two strips containing the test patches appear to lie in parallel planes, and so they should be receiving similar illumination.

Perhaps the intrinsic image story can be saved by appealing to the notion of local consistency without global consistency, such as occurs in figure 24.9. However, it may be that the main effects are the result of simpler 2D computations. The ψ -junctions, taken as 2D configurations, could be used as grouping cues that define the context in which lightness is assessed, as indicated in figure 24.10d. If this is correct, the Helmholtzian approach is overkill.

A number of investigators have lately argued for models based on Gestalt-like grouping mechanisms (e.g., Ross and Pessoa, in press). Gilchrist, who in earlier years took a Helmholtzian stance (Gilchrist and Jacobsen, 1983), has recently proposed a model of lightness that emphasizes 2D configuration and grouping mechanisms (Gilchrist et al., in press).

Anchoring and frameworks

Gilchrist's new model took shape in the course of his investigations into *anchoring*. The anchoring problem is this: Suppose an observer determines that patch x has four times the reflectance of patch y . This solves part of the lightness problem, but not all of it; the absolute reflectances remain unknown. An 80% near-white is four times a 20% gray, but a 20% gray is also four times a 5% black. For absolute judgments one must tie down the gray scale with an anchor, i.e., a luminance that is mapped to a standard reflectance such as midgray or white.

Land and McCann, having encountered this problem with Retinex, proposed that the highest luminance should be anchored to white. All other grays could then be scaled relative to that white. This is known as the *highest-luminance rule*.

Li and Gilchrist (in press) tested the highest-luminance rule using bipartite ganzfelds. They painted the inside of a large hemispherical dome with two shades of gray paint. When subjects put their heads inside, their entire visual fields were filled with just two luminances. A bipartite field painted black and gray appeared to be a bipartite field painted gray and white, as predicted by the highest-luminance rule.

By manipulating the relative areas of the light and dark fields, Gilchrist and Cataliotti (1994) found evi-

FIGURE 24.11 Simultaneous contrast is enhanced with articulated surrounds, as shown below.

dence for a second, competing anchoring rule: The largest area tends to appear white. They argue that the actual anchor is a compromise between these rules.

Gilchrist also emphasizes the importance of *articulation* and *insulation* in anchoring. Articulation is a term used earlier by Katz (1935); it refers to the number of distinct surfaces or patches within a region. Katz observed that greater articulation leads to better lightness constancy, and Gilchrist proposes that it leads to better local anchoring. We can demonstrate the effect of articulation with a simultaneous contrast display, as in figure 24.11. At the top is a standard display, with an articulated version shown below. The surround mean luminances have not changed, but the surrounds are broken into many squares. The articulated version gives a stronger illusion. In our laboratory we find that the strength of the illusory contrast can be doubled. (As with all the demonstrations in this chapter, the effect may be weaker on the printed page owing to the small image size and limitations in the printing process.)

In Gilchrist's model, anchoring occurs within a *framework*, which is a region containing patches that are grouped. Frameworks can be local or global. In figure 24.11, a local framework would be the patches surrounding the test square, and the global framework would be the entire page, and even the room in which the page is viewed.

If a local framework is well *insulated*, it has strong control over the anchoring. Insulation occurs when the local framework is strongly grouped as a separate entity from the global framework.

FIGURE 24.12 A collection of random gray surfaces will lead to different luminance distributions in different viewing conditions.

Statistical estimation

The various lightness principles might be thought of as heuristics that the visual system has arbitrarily adopted. These principles begin to make sense, however, if we consider the lightness problem from the standpoint of statistical estimation.

Suppose the world consisted of a set of gray patches randomly drawn from some distribution. Then, under a given illuminance, one would observe a distribution of luminance samples such as that shown in figure 24.12a. If the illumination were dimmed by half, then the luminances would follow suit, as shown in figure 24.12b. The arrows bracketing the distributions represent the extremes of 0% and 100% reflectance, i.e., the luminances mapping to ideal black and ideal white.

The observed luminances can also be changed by an additive haze or glare, which slides the distribution upward, as illustrated in figure 24.12c. Again, one can estimate which luminance corresponds to which reflectance; i.e., one can estimate the mapping between the observed luminance and the underlying reflectance. We use the term *atmosphere* to refer to the combined effects of a multiplicative process (e.g., illuminance) and an additive process (e.g., haze).

If one has prior knowledge about distributions of reflectances and atmospheres, one can construct optimal estimates of the locations of various reflectances along the luminance axis. That is, one can estimate the mapping between luminance and reflectance, as is required for lightness constancy.

Estimating this mapping is a central task of lightness perception. The image luminance is given and the perceived reflectance (lightness) must be derived. Anchoring

FIGURE 24.13 Lightness computations may employ adaptive windows.

is a way of describing part of this process. We will return to this problem when we discuss lightness transfer functions.

Adaptive windows

A larger number of samples will lead to better estimates of the lightness mapping. To increase N , the visual system can gather samples from a larger window. However, the atmosphere can vary from place to place, so there is a counterargument favoring small windows.

Suppose that the visual system uses an adaptive window to deal with this tradeoff. The window grows when there are too few samples and shrinks when there are more than enough. Consider the examples shown in figure 24.13. In the classical SC display, figure 24.13a, there are only a few large patches, so the window will tend to grow. In the articulated SC display, figure 24.13b, the window can remain fairly small.

Lightness estimates are computed based on the statistics within the adaptive window. In the classic SC display, the window becomes so large that the statistics surrounding either of the test patches are rather similar. (In Gilchrist's terminology, the global framework dominates). In the articulated display, the windows can be small, so that they will not mix statistics from different atmospheres. This predicts the enhancement in the illusion.

It is reasonable to assume that the statistical window has soft edges. For example, it could be a 2D Gaussian hump centered at the location of interest. Since nearby patches are likely to share the same atmosphere, proximity should lead to high weights, with more distant patches getting lower weights (cf. Reid and Shapley, 1988; Spehar, DeBonet, and Zaidi, 1996). The dashed lines in figure 24.13 would indicate a level line of the Gaussian hump.

A further advantage occurs if the adaptive window can change shape. For example, in figure 24.13c, it

would be prudent to keep the statistical pooling within the horizontal region shown by the ellipse. This will avoid mixing luminances from the adjacent regions, which are in different lighting.

This reasoning might explain why ψ -junctions are effective at insulating one region from another. A set of ψ 's along a contour (and with the appropriate gray levels) gives a strong cue that the contour is an atmospheric boundary. The statistical window should avoid crossing such a boundary in order to avoid mixing distributions. Thus the window should configure itself into a shape like that in figure 24.13c.

Atmospheres

As noted, illuminance is only one of the factors determining the luminance corresponding to a given reflectance. Other factors could include interposed filters (e.g., sunglasses), scattering, glare from a specular surface such as a windshield, and so on. It turns out that most physical effects will lead to linear transforms. Therefore the combined effects can be captured by a single linear transform (characterized by two parameters). This is what we call an atmosphere. The equation we use is

$$L = mR + e$$

where L and R are luminance and reflectance, m is a multiplier on the reflectance, and e is an additive source of light. The value of m is determined by the amount of light falling on the surface, as well as the proportion of light absorbed by the intervening media between the surface and the eye.

The equation here is closely related to the linear equation underlying Metelli's episcotister model (Metelli, 1974) for transparency, except that there is no necessary coupling between the additive and multiplicative terms. The parameters m and e are free to take on any positive values.

An atmosphere may be thought of as a single transparent layer, except that it allows a larger range of parameters. It can be amplifying rather than attenuating, and it can have an arbitrarily large additive component.

In our usage, "atmosphere" simply refers to the mapping, i.e., the mathematical properties established by the viewing conditions without regard to the underlying physical processes. Putting on sunglasses or dimming the lights has the same effect on the luminances, and so leads to the same effect on atmosphere. To be more explicit about this meaning, we define the *atmospheric transfer function*, or *ATF*, as the mapping between reflectance and luminance.

Figure 24.14 shows a set of random vertical lines viewed in three different atmospheres. The large outer

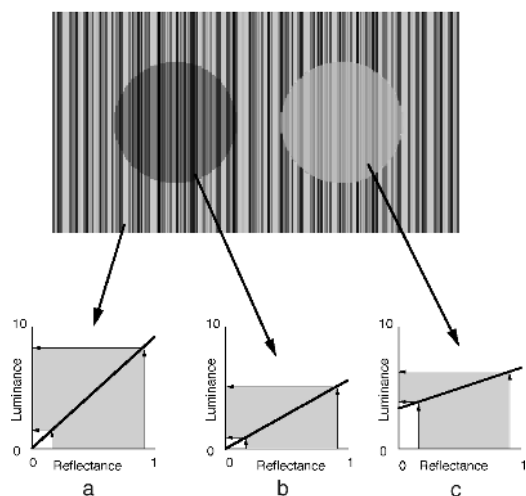

FIGURE 24.14 Lines of random gray, viewed under three different atmospheres. The ATF's, shown below, determine the mapping from reflectance to luminance.

region is in some default atmosphere. The left disk is in an attenuating atmosphere (compared to the default). The right disk is in a hazy atmosphere.

The ATF for the main atmosphere is shown in figure 24.14a. It passes through the origin, meaning that e is zero. The slope is specified by m . (Note: Since reflectance and luminance are in different units, there is also a scale constant that depends on the chosen units.) The small arrows in the panels show how the various reflectances are mapped to their corresponding luminances. The shaded area within the arrows shows how a typical range of reflectances will be mapped into the corresponding range of luminances.

Figure 24.14b shows the ATF for the dimmer atmosphere. The slope is reduced, and the intercept remains zero. On the right, in figure 24.14c, is the ATF of the hazy atmosphere. The output luminance range is compressed by m and shifted up by e .

Note that there is no such thing as a “non-atmosphere.” An observer cannot see the reflectances “directly,” but rather requires an atmospheric transfer function to convert reflectances to luminances. The parameters of the ATF always have values.

Finally, note that the (m, e) parametrization has no privileged status. Any two numbers will do. For example, a useful alternative would be the white-point and the black-point.

Since the atmosphere maps a reflectance to a luminance, the observer must implicitly reverse the mapping, turning a luminance into a perceived reflectance, as illustrated in figure 24.15. The inverting function, for a given observer in a given condition, may be called the

FIGURE 24.15 The inverse relation between the atmospheric transfer function and the ideal lightness transfer function.

lightness transfer function, or *LTF*. The LTF is subjective; it need not be linear and need not be the correct inverse of the ATF. For a given observer it must be determined empirically.

Atmospheres and X-junctions

The connection between X-junctions and atmospheres is shown in figure 24.16. Different types of atmospheres lead to different ordinal categories of X-junctions (cf. Beck, Prazdny, and Ivry, 1984; Adelson and Anandan, 1990; Anderson, 1997).

Figure 24.16a shows a region with two shades of gray paint. The large light square has 75% reflectance and the small dark square in the corner has 25% reflectance. The two reflectances are marked with arrows on the abscissa of the corresponding ATF diagram, below. Figure 24.16b shows what happens when a new atmosphere is introduced in the central patch. The new ATF is shown in a dashed line in the ATF diagram; it might be produced by a dark filter or a shadow. The resulting luminances form an X-junction of the “sign-preserving” or “nonreversing” type (Adelson and Anandan, 1990), which is consistent with transparency.

Figure 24.16c shows a different category of X-junction: the single-reversing X. It gives the impression of a murky or hazy medium. For a single-reversing X, the new ATF must cross the original ATF at a point between the two reflectances. A crossover ATF can only arise from an additive process combined with an attenuative process, such as would occur with smoke or a dirty window. Another difference between single-reversing and sign-preserving Xs is that either edge of a sign-preserving X is potentially an atmospheric boundary, while only one edge of a single-reversing edge can be an atmospheric boundary. For this reason, the depth ordering of a single-reversing X is unambiguous.

Finally, figure 24.16d shows a double-reversing X, which does not look transparent. The ATF needed to produce this X would require a negative slope. This cannot occur in normal physical circumstances. Double-reversing X-junctions do not signal atmospheric

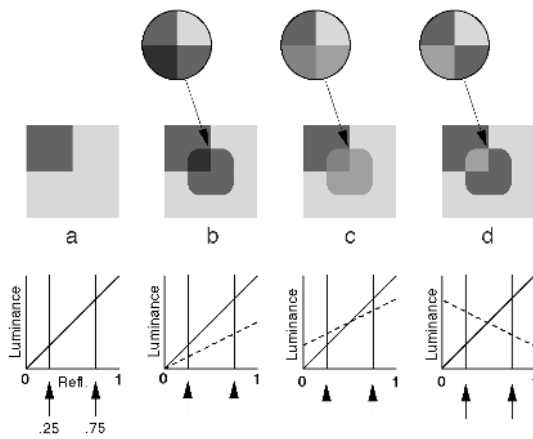

FIGURE 24.16 Transparency involves the imposition of a new atmosphere. The resulting X-junction category depends on the atmospheric transfer function.

boundaries to the visual system, and they typically look like paint rather than transparency. The junctions in a checkerboard are double-reversing Xs.

The ATF diagrams offer a simple graphical analysis of different X-junction types, and show how the X-junctions can be diagnostic of atmospheric boundaries.

Figure 24.17 shows an illusion using X-junctions to make atmospheres perceptible as such. The centers of the two diamond-shaped regions are physically the same shade of light gray. However, the upper one seems to lie in haze, while the lower one seems to lie in clear air.

The single-reversing Xs surrounding the lower diamond indicate that it is a clearer region within a hazier region. The statistics of the upper region are elevated and compressed, indicating the presence of both attenuative and additive processes. Thus the statistical cues and the configural cues point in the same direction: The lower atmosphere is clear while the upper one is hazy.

The shifted Koffka rings

It is useful at this point to recall the modified Koffka display of figure 24.6c. When the two halves are slid vertically, a set of sign-preserving X-junctions is created along the vertical contour. The junctions are consistent with transparency, and the contour becomes a strong atmospheric boundary between the left and right regions. The two semicircles are seen within different frameworks. The statistics on the two sides are different. In addition, grouping cues such as good continuation indicate that the left semicircle is connected to the light region on the right, and the right semicircle is connected to the dark region on the left. Thus there are several cues that conspire to make the two semicircles look quite different.

FIGURE 24.17 The haze illusion. The two marked regions are identical shades of gray. One appears clear and the other appears hazy.

T-junctions and White's illusion

White's illusion is shown in figure 24.18. The gray rectangles are the same. This is surprising: By local contrast, the left ones should look darker than the right ones. The left rectangles have a long border with white and a short border with black. The illusion is reversed from the usual direction. This effect has been interpreted in terms of the T-junctions (Todorovic, 1997; Gilchrist et al., in press). Patches straddling the stem of a T are grouped together for the lightness computation, and the crossbar of the T serves as an atmospheric boundary (cf. Anderson, 1997, for an alternative approach).

Zaidi, Spehar, and Shy (1997) have shown that the action of T-junctions can be so strong that it overpowers traditional grouping cues such as coplanarity. Therefore the grouping rules for the lightness computation evidently differ from those underlying subjective belongingness.

Constructing a new illusion

One can intentionally combine statistical and configural cues to produce large contrast illusions. In the "criss-cross" illusion of figure 24.19, the small tilted rectangles in the middle are all the same shade of gray. Many peo-

FIGURE 24.18 White's illusion. The gray rectangles are all the same shade of gray.

ple find this hard to believe. The figure was constructed by the following principles: The multiple ψ -junctions along the vertical edges establish strong atmospheric boundaries. Within each vertical strip there are three luminances and multiple edges to establish articulation. The test patch is the maximum of the distribution within the dark vertical strips, and the minimum of the distribution within the light vertical strips. The combination of tricks leads to a strong illusion.

Each ψ -junction, by itself, would offer evidence of a 3D fold with shading. However, along a given vertical contour the ψ 's point in opposite directions, which discourages the folded interpretation. Some observers see the image in terms of transparent strips; others see it merely as a flat painting. However, all subjects see a strong illusion instantly. Thus, a 3D folded percept is not necessary: The illusion works even when "a ψ is just a ψ " (Hupfeld, 1931).

The snake illusion

Similar principles can be used to construct a figure with X-junctions. Figure 24.20a shows an illusion we call the

FIGURE 24.19 The crisscross illusion. The small tilted rectangles are all the same shade of gray.

snake illusion (Somers and Adelson, 1997). The figure is a modification of the simultaneous contrast display shown at the right. The diamonds are the same shade of gray and they are seen against light or dark backgrounds. A set of half-ellipses has been added along the horizontal contours. The X-junctions aligned with the contour are consistent with transparency, and they establish atmospheric boundaries between strips. The statistics within a strip are chosen so that the diamonds are at extrema within the strip distributions. Note that the ellipses do not touch the diamonds, so the edge contrast between each diamond and its surround is unchanged.

Figure 24.20b shows a different modification in which the half-ellipses create a sinuous pattern with no junctions and no sense of transparency. The contrast illusion is weak; for most subjects it is almost gone. Thus, while figures 24.20a and 24.20b have the same diamonds against the same surrounds, the manipulations of the contour greatly change the lightness percept. In effect, we can turn the contrast effect up or down by remote control.

Why should the illusion of figure 24.20b be weaker than in the standard SC? We have various observations suggesting that the best atmospheric boundaries are straight, and that curved contours tend to be interpreted

FIGURE 24.20 The snake illusion. All diamonds are the same shade of gray. (a) The regular snake: the diamonds appear quite different. (b) The "anti-snake": the diamonds appear nearly the same. The local contrast relations between diamonds and surrounds are the same in both (a) and (b).

as reflectance. The sinuous contours of figure 24.20b are not seen as atmospheric boundaries, and therefore the adaptive window is free to grow and to mix statistics from both light and dark strips.

Summary

Illusions of lightness and brightness can help reveal the nature of lightness computations in the human visual system. It appears that low-level, mid-level, and high-level factors can all be involved. In this chapter we have emphasized the phenomena related to mid-level processing.

Our evidence, along with the evidence of other researchers, supports the notion that statistical and configurational information are combined to estimate the lightness mapping at a given image location. In outline, picture looks like this:

- At every point in an image, there exists an apparent atmospheric transfer function (ATF) mapping reflectance into luminance. To estimate reflectance given luminance, the visual system must invert the mapping, implicitly or explicitly. The inverting function at each point may be called the lightness transfer function (LTF).
- The lightness of a given patch is computed by comparing its luminance to a weighted distribution of neighboring luminances. The exact computation remains unknown.
- Classical mechanisms of perceptual grouping can influence the weights assigned to patches during the lightness computation. The mechanisms may include proximity, good continuation, similarity, and so on. However, the grouping used by the lightness system apparently differs from ordinary perceptual grouping.
- The luminance statistics are gathered within an adaptive window. When the samples are plentiful, the window remains small; but when the samples are sparse, the window expands. The window is soft-edged.
- The adaptive window can change shape and size in order to avoid mixing information from different atmospheres.
- Certain junction types offer evidence that a given contour is the result of a change in atmosphere. The contour then acts as an atmospheric boundary, preventing the information on one side from mixing with that on the other. A series of junctions aligned consistently along a contour produces a strong atmospheric boundary. Some evidence suggests that straight contours make better atmospheric boundaries than curved ones.

25 High-Level Vision as Statistical Inference

DANIEL KERSTEN

ABSTRACT Human vision is remarkably versatile and reliable, despite the fact that retinal image information is noisy, ambiguous, and confounds the properties of objects that are useful. By treating vision as a problem of statistical inference, three classes of constraints can be identified: the visual task, prior knowledge of scene structure independent of the image, and the relationship between image structure and task requirements. By considering the visual system as an organ for statistical inference, we can test whether and how it uses these constraints. This strategy is illustrated for two high-level visual functions: depth-from-cast-shadows and viewpoint compensation in 3D object recognition.

An object's relative depth can be determined from its cast shadow, even when local image information doesn't uniquely specify shadow edges and global information doesn't determine where the light source is. What information enables a unique estimate of depth from shadows? This chapter shows how the visual task, prior assumptions on light source movement and material properties, and local image cues constrain the perception of depth from shadows.

A 3D object can be recognized from views never seen before, despite the fact that depth information about shape is lost due to projection onto the retina. How does human recognition compensate for variations in viewpoint? By designing a simple recognition task for which optimal statistical decisions are computable, human performance can be normalized with respect to the information in the task, leaving remaining differences diagnostic of brain mechanisms.

High-level vision is often divided into two primary functions: object recognition and localization. Although these visual functions have quite different processing demands, they are linked by a common framework of statistical inference. The need for such a framework spans the levels of visual processing (see figure 25.1), and is due to the inherently statistical relationship between the image measurements at the eye and properties of objects in the world. The statistical problem of vision is both geometric and photometric: The depth dimension is lost owing to projection onto the retina, and information about the geometry of objects gets entangled with photometric information about object ma-

terial and illumination. Image intensity at a point is a complex function of object shapes, materials, illumination, and viewpoint (see figure 25.2). As a result, information about the world is encrypted in the pattern of image intensities and any single source of local image information is only probabilistically related to its causes. This chapter takes seriously the idea that vision consists of brain processes that decrypt image patterns through statistical inference (Kersten, 1990; Yuille and Bülthoff, 1996). Perception as inference has a long history; however, it is with the advent of computer vision that we have begun to understand the inherent complexity of visual inference from natural images and to develop and apply the theoretical principles of perceptual inference (Clark and Yuille, 1990; Knill and Richards, 1996).

Much of our knowledge of the visual system has come through an analysis of early stages of processing in which we try to understand how local contours (defined by intensity, color, texture, disparity, or motion) are grouped to define objects. Consider figure 25.1 for example. Here we see how local constraints of edge collinearity and transparency determine the way contours are grouped in a simple figure, with the result that one sees either overlapping ape faces or nonoverlapping human faces. Research in computer vision has shown, however, that edge detection and object segmentation from natural images is a harder problem. Even apart from ubiquitous image and neural noise, the response of an optimally tuned oriented spatial filter (e.g., simple cell in visual cortex) does not uniquely determine whether the corresponding edge in the scene is due to a shadow, specularity, or a change in depth, orientation, or material (see figure 25.3). Yet such distinctions are crucial for visual function. Adaptive visual behavior depends on reliable decisions regarding object shape, material, and spatial relationships (figure 25.2). Because of the inherent ambiguity in the eye's input regarding these scene properties, vision is sometimes said to be an ill-posed problem. In contrast, the brain has clearly solved the problem—but how? The answers lie both in

DANIEL KERSTEN Department of Psychology, University of Minnesota, Minneapolis, Minn.

FIGURE 25.1 Different levels of perceptual processing. Vision is often divided into low-, middle-, and high-level levels of processing. Consider the upper left panel, which is usually (but not always) seen as the overlapping profiles of two simians. Low-level vision detects local image features, such as short oriented line segments or corners. Middle-level vision groups image features likely to belong to the same object. High-level vision refers to the type of visual function (e.g., depth perception or object recognition). Here, for example, the grouping is seen either as the overlapping face profiles of two simians or as two human faces. The interpretation of the figure depends on interactions across levels involving visibility of local features, constraints on grouping, and prior expectations on simian and human profiles. For example, middle-level constraints determine how the four lines meeting at the two X-junctions are grouped. A constraint of collinearity interprets the X-junction as two crossing straight lines (rather than touching corners), which is consistent with the simian percept. But a strong prior preference for human profiles can override this middle-level constraint. If the two halves are separated down the middle (lower left panel), one can easily see the other interpretation of two humans. Local constraints on transparency also affect how the contours are grouped (two right panels).

the nature of visual mechanisms and in the theme of this chapter—the information that enables and constrains reliable visual inference.

1. Natural constraints and visual decisions

One can identify three types of constraints that make reliable visual inference possible: the visual task, prior knowledge of scene structure independent of the image, and the relationship between image structure and task requirements. Bayesian decision theory provides a precise language to model these constraints (Yuille and Bülthoff, 1996). Here we postpone discussion of the visual task and suppose that the image measurements, \mathbf{I} , and the required scene parameters, \mathbf{S} , useful for the task have been specified. The knowledge for visual inference is characterized by the posterior probability density, $P(\mathbf{S}|\mathbf{I})$, which models the probability of a scene description \mathbf{S} , given the image data, \mathbf{I} . By Bayes' rule,

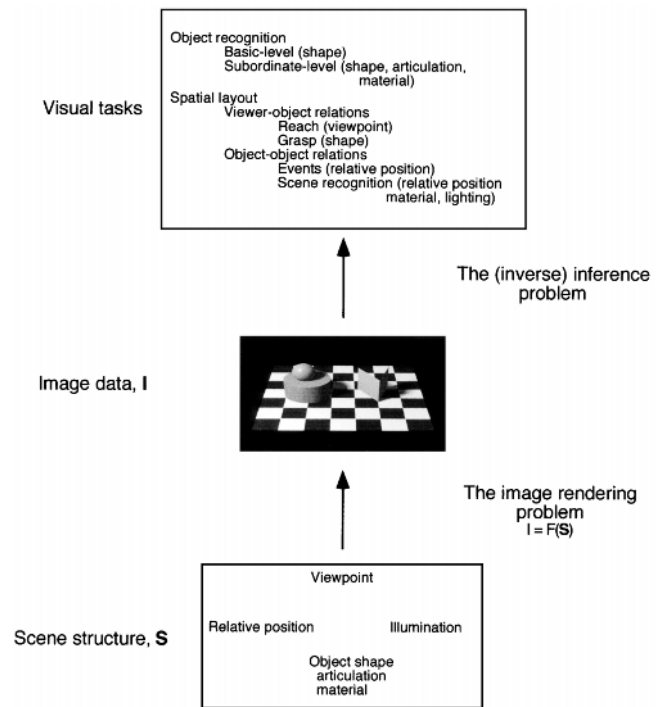

FIGURE 25.2 Constraints on visual inference. Information about object shape, articulation, material, illumination, and viewpoint is encrypted in the image through rendering and projection. Diverse visual tasks depend on estimates of these scene variables. Some scene variable estimates are more important for some tasks than others. The important variables for a task are the *explicit* variables. Variables to be discounted are referred to as *generic*. For example, it is commonly assumed that shape—but not viewpoint, illumination, or material—should be estimated explicitly for basic-level recognition (e.g., deciding whether an image is that of a dog, rather than a particular dog, “Snuggles”). Viewpoint and illumination are generic variables for object recognition at all levels. Hypothesized explicit variables are indicated in parentheses for various visual tasks (top box). The visual task, the nature of the projection of the scene onto the image, and the scene structure probabilities characterize the knowledge required for decoding image data.

the posterior is

$$P(\mathbf{S}|\mathbf{I}) = \frac{P(\mathbf{S})P(\mathbf{I}|\mathbf{S})}{P(\mathbf{I})} \\ \propto P(\mathbf{S})P(\mathbf{I}|\mathbf{S}) \quad P(\mathbf{S})P(\mathbf{I} - F(\mathbf{S}))$$

where $P(\mathbf{I})$ is fixed for a given image measurement.

$P(\mathbf{S})$ is the prior density modeling the scene. In theory, a prior scene model could be realized as an algorithm to produce samples of scenes—including objects, materials, and illuminations—independent of the images that might result. In practice, density models are limited to subdomains such as surface smoothness, shape, contour, or material (Kersten, 1991; Poggio, Torre, and Koch, 1985; Sha’ashua and Ullman, 1988; Zucker and

FIGURE 25.3 A measurement of a local change of image intensity, illustrated by the elliptical patch in the upper left, is highly ambiguous as to what in the scene caused it. A change in material, depth, surface orientation, specularity, or shadow can create the same local oriented intensity change, up to a spatial scale factor. (Adapted from Kersten, 1997.)

David, 1988), or specific object domains (e.g., human facial surfaces via principal components analysis; cf. Vetter and Troje, 1997). From the standpoint of inference, knowledge of prior constraints eliminates alternative image interpretations that are consistent with the image data. Once formulated, one can test whether human perception employs the prior constraints (Mamassian and Landy, 1998; Weiss and Adelson, 1998). Later, in section 2, we'll see how the assumption that light sources are usually above objects affects the perception of depth from cast shadows.

$P(\mathbf{I}|\mathbf{S})$ is the likelihood of the image measurements given a scene description. The likelihood is determined by how images are formed—the image rendering problem of computer graphics, $\mathbf{I} = F(\mathbf{S})$.¹ A common example of the likelihood constraint is that straight lines in the scene project to straight lines in the image. The likelihood also provides the tools for reducing ambiguity through cue integration (Landy et al., 1995). *A priori* knowledge of the scene would seem to be required to develop an explicit model of the image. However, Bayes provides tools for learning representations of the image, bottom-up (e.g., Olshausen and Field, 1996; Zhu, Wu, and Mumford, 1997). Mumford (1995) has proposed that minimum description length encoding (formally equivalent to Bayes' maximum *a posteriori* estimation²) may provide a general means to discover world structure from images. Specific task requirements can also be used to discover useful image features (e.g., Belhumeur, Hespanha, and Kriegman, 1996). These image-based approaches are important because the problems are posed in a form closer to those of natural adaptation and development. But ultimately, the statistical structure of images derives from how images are formed from the scene.

Let's return to the question of how knowledge of the visual task reduces ambiguity in visual inference.

SPECIFYING THE TASK: EXPLICIT AND GENERIC VARIABLES Visual problems are often said to be ill-posed when there are more scene parameters to estimate than data. In this case, priors are essential to find unique solutions. However, for specific functional goals, such as visual tracking or face recognition, the number of parameters can be drastically reduced (Blake and Yuille, 1992). With a good representation, the prior is constant, and the decision can be made on the likelihood alone. One still faces the problem that image intensities confound all of the scene variables, both the irrelevant and those required for the task. The relevant and irrelevant scene variables are called explicit and generic, respectively.³ The general idea is that different visual tasks require a more explicit or precise representation of some scene parameters than others (Brainard and Freeman, 1994; Freeman, 1994; Yuille and Bülthoff, 1996; Hurlbert, Bloj, and Kersten, submitted; figure 25.2, upper box). For example, object recognition relies on an estimation of shape, with viewpoint discounted (section 3). But discounting is not ignoring, and one would like estimates of the scene that are insensitive to the generic variables. In fact, with certain assumptions, finding the most likely estimate of the posterior density of the explicit variable has an appealing intuitive interpretation (Freeman, 1994): Perception's model of the image should be robust over variations in generic variables.⁴ This is a generalization of the generic view principle (Lowe, 1985; Nakayama and Shimojo, 1992) and follows from statistical decision theory. Note that, as stated, a literal implementation would be top-down, because it would require measuring variations in the image domain. Section 2 shows how specifying depth and illumination direction as explicit and generic variables, respectively, reduces ambiguity in depth-from-shadows.

The posterior probability defines the visual information available, but one must still extract estimates and decisions according to some criterion. In section 2, we estimate depth from shadows by picking the depth that is most probable. A visual task can also be a simple decision, which makes for good psychophysics. In section 3, we ask humans and a statistically ideal observer to maximize the percent correct in answering the question: Is this the right object?

THE UTILITY OF TREATING VISION AS BAYESIAN INFERENCE The Bayesian framework has much to offer: It requires one to describe all the assumptions that constrain the visual inference; it specifies quantitative models at a level appropriate for psychophysics, avoiding premature

commitment to neural mechanisms; and it provides a common language for psychophysics (Knill and Kersten, 1991) and neural network modeling (Bishop, 1995; Ripley, 1996). A weakness of a Bayesian analysis is that, while prescribing the constraints, it doesn't say how they are embedded in visual mechanisms. However, comparison of human and ideal observers provides hints for neural model implementations, as shown in the object recognition example discussed below.

The rationale for using the Bayesian inversion of the posterior probability is that, although the image rendering constraint is unambiguous, it is usually easier to determine than the inverse. But does Bayes suggest more than a theoretical convenience? It has been argued that the inherent confounding of diverse scene causes in natural patterns, including images, necessitates analysis-by-synthesis through a generative model that tests top-down predictions of the input. One commonly discussed explanation for the pattern of backprojections between cortical areas is that these connections enable the expression of unresolved high-level hypotheses in the language of an earlier level (Mumford, 1994; Dayan et al., 1995). This expression can then be tested with respect to the incoming data at the earlier level. Thus, domain-specific models in memory can be manipulated to check for fits to the incoming data in ways that are difficult bottom-up. We return to this issue below in the discussion of human object recognition mechanisms.

APPLYING THE STATISTICAL INFERENCE APPROACH TO HIGH-LEVEL VISION We have seen that characterizing the statistical requirements for reliable visual inferences is a complex problem. It requires modeling the signals the world is sending about object shape, material, and location; the way in which the signals get “muddled” in the form of an image; and the optimal means to decode this image. Solving these problems using Bayes’ methods for general-purpose vision is not yet feasible. Practical applications to high-level human vision require either (1) a judicious approximation of a natural visual task and qualitative analysis of natural constraints or (2) designing a computable psychophysical task. The latter approach has a successful history in studies of early visual mechanisms (e.g., Barlow, 1962; Geisler, 1989; Knill, 1998; Pelli, 1990; Schrater, Knill, and Simoncelli, 1998) and recent applications to the high-level visual tasks of reading (Legge, Klitz, and Tjan, 1997) and object recognition (Tjan et al., 1995).

Section 2 describes a qualitative analysis of depth-from-cast-shadows, a problem in spatial layout where resolving ambiguity in edge identity is crucial (Knill, Kersten, and Mamassian, 1995). Realistic computer graphics allow the approximation of natural complexity

FIGURE 25.4 Depth-from-cast-shadows. Observers viewed computer animations in which a central square was held fixed in the image, while its shadow moved diagonally back and forth from the center outwards. The simulations were produced by moving the central square back and forth directly along the line of sight. By using orthographic projection, the image size is independent of depth and thus remained constant. The upper panel shows first and last frames for the main condition, in which the illumination was from an extended light source above and to the left of the square. The middle panel shows final frames for this condition, as well as three others. From left to right, the conditions are: extended light source from above, extended light source from below, point light source from above, and point light source from below. The extended light source (e.g., a fluorescent panel) produces a penumbra that gets fuzzier as the square gets farther away from the background. Despite the lack of objective image motion of the central square, it almost always appeared to move in depth for the extended-light-from-above condition. The bar graph (lower panel) shows the proportion of times (out of 15) observers reported the central square patch to be moving in depth for extended and point light sources from above or below. There is a significant advantage of an extended light versus a point source ($z = 2.28$, $p < .02$), and of light from above versus below ($z = 3.028$, $p < .002$). A QuickTime™ movie demonstrating illusory motion from shadows can be viewed and downloaded from: <http://vision.psych.umn.edu/www/kersten-lab/shadows.html>. (Adapted from Kersten et al., 1996.)

while retaining sufficient simplicity to analyze the image ambiguities and identify natural constraints. Section 3 describes an investigation of the problem of viewpoint variation in object recognition, where the second

FIGURE 25.5 Ambiguities of material and spatial layout for the depth-from-shadows movies. Assume the central square, the “shadow,” and background of figure 25.4 have been segmented, but not labeled according to whether they are opaque material, transparent material, or shadow. Image formation constraints guarantee that the central square and the dark shadow regions lie somewhere along the line of sight—but where? The background could be transparent and in front of the shadow (a), rather than the reverse (b or c). If outside the eye’s depth-of-field, the ersatz shadow image would mimic the fuzziness of a penumbra change. If the shadow patch was instead a transparent surface, it could be at location b or c; but if a shadow, it would have to be at b. Occlusion cues place the square in front of the background. For a reliable inference of depth-from-shadows, the shadow has to be labeled as such, localized to the background, and linked to the casting object. And then one is left with two more questions: Where is the light source, and is the motion in the image due to movement of the light source or the central square (see figure 25.6).

approach, often called *ideal-observer* analysis, is adopted (Liu and Kersten, 1998; Liu, Knill, and Kersten, 1995). A key issue is how recognition overcomes the geometric problem of projection. Ideal-observer analysis provides a rigorous means to normalize human performance with respect to the informational limits imposed by the task itself, and thereby draw firm conclusions about the underlying mechanisms.

2. Depth-from-cast-shadows: *Qualitative analysis of constraints*

One can list more than a dozen cues to depth, including stereo disparity, motion parallax, and the pictorial cues. One of the pictorial cues, depth-from-cast-shadows, is particularly interesting because it is surprisingly strong for human perception (under some conditions dominating motion or stereo; Kersten et al., 1996) and seems to involve a complex set of inferences, which we explore below (Kersten, Mamassian, and Knill, 1997; Mamassian, Knill, and Kersten, 1998). From a theoretical standpoint, we do not yet have a quantitative theory of how to compute depth from shadows, even in principle. This is in contrast to depth from stereo disparity or mo-

FIGURE 25.6 The visual task constrains the estimate of relative depth-from-shadows. This figure shows a very simplified view of the geometric constraints where we’ve assumed that the remaining unknowns are the light source direction, α , and relative depth, z . By treating light source direction as a generic variable, one can show that the best bet for the target depth is $z = x$.

tion parallax where the computational problems are well-understood.

To investigate depth-from-shadows experimentally, Kersten and colleagues (1996) made a movie of a square in front of a stationary checkerboard illuminated with an extended light source (figure 25.4, top panel). The central square was fixed in the image, and the only movement was that of a shadow translating diagonally away and then back to the square. Despite the square’s lack of motion, observers reported an initial strong perception of the square moving in depth. The computer animation looks realistic and the perceptual interpretation unique, yet the image data have significant ambiguities of material and depth (figure 25.5), and of light source motion and direction (figure 25.6). This simple percept involves a range of decisions across several levels of abstraction. Let’s consider, in turn, inferences of (1) context, (2) motion event, (3) image region categorization, and (4) depth parameter estimation.

1. A key question of context is: Which of the objects or viewer provides the frame of reference with which to interpret the locations of the other object(s)? Viewpoint should be generic for deciding whether the square is headed away from the checkerboard, but explicit if the task is to reach to the square. The central square, not the background, appears to move. Relative size, enclosure, and occlusion information in the image may all provide support for the decision that the checkerboard provides a stationary frame of reference. The decision that the background is opaque (see figure 25.5) must involve a prior default on material, because the same image could

have resulted from a transparent background and opaque “shadow”—a percept which can be seen given training (Kersten et al., 1992).

2. At some level, an object–shadow “event” must be identified. This could involve combining independent identifications of surface and shadow image regions, or using global image information. Other experiments suggest that characteristic correlated motion, an image formation constraint, may be a global diagnostic for a moving object–shadow pair because of its robustness with respect to viewpoint variation (Kersten, Mamassian, and Knill, 1997). For moving objects, the linkage between the object and its shadow is strongly constrained by a prior assumption that light sources usually don’t move. The assumption that light sources are usually from above accounts for the finding that shadows above the object are less effective than those below (figure 25.4)—an assumption well known for shape-from-shading (Gibson, 1950).

3. Computing relative depth depends on either an explicit or implicit categorization of image regions as opaque surface, transparent surface, or shadowed surface. A particularly diagnostic cue for motion in depth is the changing fuzziness of the penumbra caused by an extended light source. This was the most effective condition in figure 25.4. Such a local image measurement has less ambiguity with other scene causes (e.g., it is less likely to be confused with a material change, although it could result from surface edge motion out of the depth-of-field range, or a spreading stain). This cue is also robust over viewpoint, and a large range of types of illumination. In contrast, the sharp shadow is often seen as a transparent surface—a decision also supported by local transparency constraints at X-junctions (Metelli, 1975). Physically unnatural light “shadows” violate local transparency constraints consistent with shadows and lead to less effective apparent motion (Kersten, Mamassian, and Knill, 1997). Occlusion of the shadow by the object is a potentially important constraint for determining which patch of the object–shadow pair is the shadow; however, occlusion isn’t necessary for depth-from-cast-shadows.

Local cues supporting a shadow hypothesis have to be weighed against the conflicting cues regarding motion in depth. Size change and velocity in the image are both zero, indicating no motion in depth. This is a consequence of viewpoint’s being a generic variable. The alternative interpretation is of a square moving directly along the line of sight, but this is normally ruled out because small changes in viewpoint would produce large changes in the image. The fact that depth change with shadow motion is seen is evidence of a strong prior stationary light source constraint.

4. A visual estimation can be made as to the square’s location or velocity from the measured shadow location or velocity. Suppose the object–shadow pair is detected, the shadow identified and localized to the background surface. The stationary light source assumption would resolve ambiguity regarding motion in depth. But what about a stationary case? Where is the light source?

THE VISUAL TASK CONSTRAINS AN ESTIMATE OF RELATIVE DEPTH: ROBUSTNESS WITH RESPECT TO GENERIC VARIABLES Consider the simple geometric ambiguity illustrated in figure 25.6. The measured displacement, x , between the image of an object and its shadow can be caused by an infinite number of combinations of object distance, z , and light source direction, α : $x = z \tan(\alpha)$. An additional constraint is required to estimate z from x . One could try to measure (or make up) a prior on the light direction that would produce a unique estimate of z . But the task itself provides a sufficient constraint to uniquely estimate z . Assume that the explicit variable is relative depth z , and the generic variable is light source direction α . By differentiating the above geometric constraint on object, shadow, and light source parameters (see note 4), we have $\Delta x = \Delta \alpha (x^2 + z^2) / z$. For a given variation $\Delta \alpha$, the minimum change in Δx would occur for $z = x$. Perception’s estimate of shadow displacement is most robust to variations in light direction for relative depths equal to the displacement, i.e., equivalent to assuming the light is at 45 degrees. At this point, we do not know the generality or precision with which the robustness principle predicts human estimates of depth-from-shadows, our point being to illustrate how task requirements reduce ambiguity. However, in the domain of color constancy, treating illumination direction as a generic variable has been shown to quantitatively predict color matches contingent on the mutual illumination between surfaces (Hurlbert, Bloj, and Kersten, submitted).

3. Viewpoint compensation in 3D object recognition: Ideal-observer analysis

A basic component of 3D object recognition is a process that verifies matches between the input stimulus and stored object representations in memory. The problem is that the images of a single object are enormously variable, depending on viewpoint, among other factors. The visual system must somehow compensate for such variations in order to identify an object as the same when seen from another viewpoint. There has been recent debate regarding the nature of these stored representations and the mechanisms that test for a match. On the one hand, certain object properties such as edge straightness are preserved in the image over

viewpoint changes, suggesting that the early extraction of such features could be used fairly directly (Biederman, 1987; Hummel and Biederman, 1992). On the other hand, computer vision has shown the difficulties in extracting features such as edges from natural images. Further, the experimental observation that familiar views of an object are processed more effectively than unfamiliar views suggests that the memory of an object may be closely tied to images previously seen of that object (Bülthoff and Edelman, 1992; Tarr and Bülthoff, 1995).

How does the visual system compensate for image variations in size, position, and rotation in depth produced by an object? One can devise schemes to allow for variations in scale and position through feedforward mechanisms (Ullman, 1996). Neurons insensitive to object scale and position have been found in inferotemporal cortex of monkeys (Logothetis et al., 1994). Allowing for rotations in depth, however, seems more problematic because depth information is lost in the 2D projection, so one doesn't know how to transform the image to allow for these rotations. Let's consider two cases that differ in the degree to which 3D information is involved in a test for a match.

Suppose that an object is represented as a collection of independent 2D images or views in memory. These views have, through experience, come to be associated with each other, and have a common label. In order to recognize a novel view, similarity is measured independently between this novel view and each of the familiar views. The combination of the measurements determines if the novel view should be recognized or rejected. Although the measure of similarity has some flexibility, the crucial point is that recognition can be achieved with 2D manipulations of the images without reconstructing the 3D structure of the object either explicitly or implicitly (Bülthoff and Edelman, 1992; Poggio and Edelman, 1990). Below we describe a "smarter" version of such a model for human vision (the 2D/2D observer), which in addition allows for possible rotations in 2D for each template view.

Contrast this with a second case in which there is a candidate 3D object model in memory. Then the appropriate transformation could be applied to the model in memory, and thus compensate for rotations in depth in order to test for a match. Imagine two subcases. The most straightforward identification scheme verifies a match by translating, scaling, and rotating an explicit 3D model of the object in memory, projecting the result in a 2D image space, then using a measure of similarity to test for a satisfactory match with the 2D input (Basri and Weinshall, 1996). The statistically optimal version of this model is called a 3D/2D ideal observer (Liu, Knill, and

Kersten, 1995). Despite its intuitive simplicity, a straightforward implementation is computationally unrealistic even for simple objects—the space of transformations is just too big. However, a clever shortcut was discovered by Ullman and Basri (1991): With as few as two views one could carry out the verification process by checking the linear dependence of the input image on the two stored views.

Liu, Knill, and Kersten (1995) devised a 3D object discrimination task for which they could calculate ideal performance for the 2D/2D and 3D/2D classes of observers. By comparing human with ideal performance, they were able to factor out limitations imposed by the task itself, and thereby investigate how the human visual system compensates for viewpoint change.

Their object world was simple: Five randomly placed vertices (3D points) were connected by four straight cylinders of uniform diameter, making 3D wire prototype objects that looked like bent paper clips. A pair of objects was generated from a prototype by adding independent 3D positional Gaussian noise at the vertex points. One object is called the target, whose Gaussian noise has a fixed variance. The other is called the distractor, whose variance is always larger. In the test phase, the novel views of an object could have any orientation in space—i.e., the prior probability on rotations in 3D was uniform. The 3D/2D observer has complete knowledge of the target object and task. Prior knowledge of the target object is given in the form of 11 views to the 2D/2D observer, and to the human observers through training.

In contrast to the analysis of depth-from-cast-shadows, the task requirements for the ideal and human observers are precisely specified. Optimal recognition performance is based on the shape of the object defined by the image vertex positions (explicit variables), with viewpoint variables being generic. The task is summarized in figure 25.7. Both the human and ideal observers must choose from the two images an object that is more similar (in Euclidean distance) of the feature points to the prototype object.

3D/2D IDEAL OBSERVER Let's formalize the inference constraints for the 3D/2D ideal observer. Occlusion can be neglected because the vertex feature points for wire objects are visible from almost all viewing angles. Further, because the vertices are connected, one knows how to order the vertices when comparing stimulus to memory. The visual decision is based on a representation of the objects and images in terms of 15 and 10 dimensional vector vertex locations, respectively.

The 3D/2D ideal observer matches the stimulus image against all possible views of a known prototype object.

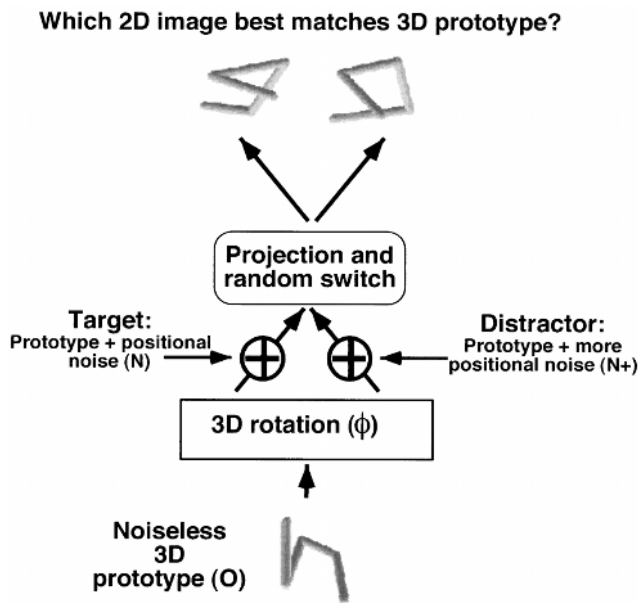

FIGURE 25.7 The 3D object classification task presented to human and ideal observers. The observers are required to discriminate between two classes of wire object—one generated by adding a small fixed amount of noise to the vertices of a prototype object (the target), and the other generated by adding a larger amount of noise to the prototype object (distractor). The means for both target and distractor sets are the same prototype object. Two stimuli were generated by a 3D rotation of the noiseless prototype. The standard deviation of the positional noise added to the distractor (prototype + more noise) was greater than that added to the signal (prototype + noise). Knowledge of the wire objects was provided in a prior training session in which the object prototype was first learned from a discrete number (11 rotations) of its images. The 11 training views of a prototype object were created by rotating the object first around the x -axis (horizontal in the screen plane) six times in 60-degree steps, and then around the y -axis (vertical in the screen plane) six times, again with 60-degree rotational steps, resulting in 11 views of the object. The angle with the z -axis was chosen from a uniform density between 0 and 180 degrees and the angle with x -axis was chosen from a uniform density between 0 and 360 degrees.

By definition, the ideal's image rendering model is

$$\mathbf{I} = F_{\Phi}(\mathbf{O}) + \mathbf{N}_p$$

where \mathbf{I} and \mathbf{O} are vector representations of the 2D vertex positions of the 2D image and 3D vertex positions of the object, respectively. $F_{\Phi}(\cdot)$ represents the combined effects of an unknown viewpoint transformation in 3D (represented by a three-component vector Φ), followed by orthographic projection. \mathbf{N}_p is the positional noise of the projected vertex positions. An ideal observer can detect only the 2D vertex positions in a stimulus image but has a full 3D model of the prototype. Such an observer would estimate the probability of obtaining image \mathbf{I}_k from the target (smaller noise variance)

by integrating out the generic viewpoint variables to obtain the probability of \mathbf{I}_k , $p_t(\mathbf{I}_k)$.⁵ To achieve the maximum average percent correct, the ideal observer chooses the image ($k = 1$ or 2) with the larger value of $p_t(\mathbf{I}_k)$.

The essence of the 3D/2D ideal observer is that it provides an exact model of the 3D object, \mathbf{O} , in memory, as well as precise knowledge of how such an object in the world could be transformed into an image, \mathbf{I} . This transformation includes the unknown generic variables of rotation. A key component in the ideal calculation is a measurement of similarity; because the noise is Gaussian, this is given by $\|\mathbf{I} - F_{\Phi}(\mathbf{T}_i)\|^2$. In theory, a straightforward implementation of the probability calculation would involve manipulations in a 3D object space followed by backprojection of the model into image space to measure the similarity. (Again, because of the large transformation space, this calculation isn't feasible; see Liu, Knill, and Kersten, 1995, for an approximation). The 2D/2D observer is an alternative way of measuring similarity—one that relies on manipulations that can, in principle, be done entirely in a 2D image space. In efficiency, it is lower than the 3D/2D observer's, but can it account for human performance?

THE 2D/2D OBSERVER In the experimental task, an observer sees 11 distinct views of the object—familiar views from which a 3D/2D observer could, in theory, construct a 3D object model, \mathbf{O} (11 is more than enough to do this). Suppose, however, that there was no mechanism to construct such a model, and the recognition system had to rely on making matches of the 11 familiar views in memory to the stimulus image. Further suppose the observer had available rigid rotations in the 2D plane to compensate for the normal image variations that arise through 3D rotations. This 2D/2D observer has the wrong image-rendering model. Yet it does its best by optimally combining information from stored multiple views under the constraint of 2D rigid transformations specified by a rotation matrix, R_{ϕ} .

Let \mathbf{I} represent the coordinates of the vertices in a stimulus image, and $\mathbf{T} = \{\mathbf{T}_1, \mathbf{T}_2, \dots, \mathbf{T}_{11}\}$ represent the 11 prototype templates. The ideal decision is based on $p_t(\mathbf{I})$ where the viewpoint compensation is restricted to the 2D image domain.⁶ Because a rotation of the model ($R_{\phi}(\mathbf{T}_i)$) is equivalent to an inverse rotation of the image ($R_{\phi}^{-1}(\mathbf{I})$) for the 2D/2D observer, variation over viewpoint can be compensated for either by feedforward or backprojection.

HUMAN PERFORMANCE Figure 25.8 shows human performance relative to the 3D/2D and 2D/2D observers for decisions based on both familiar and novel views.

FIGURE 25.8 Statistical efficiencies for human performance relative to the 3D/2D and 2D/2D observers. The error bars show ± 1 standard deviation.

Performance is measured in terms of statistical efficiency.⁷ The 3D/2D efficiency factors out the limits to performance imposed by the task itself, independent of any algorithm used to compute decisions. The 2D/2D efficiencies are expressed in the same units.

First note that 3D/2D efficiencies are much less than 100%. There are two main sources of inefficiency for humans: intrinsic noise and an inappropriate transformation process. If the only problem were some internal uncertainty added to the artificially introduced positional noise, the efficiencies for familiar and novel views would be the same. The fact that novel views are dealt with less efficiently is consistent with theories of recognition that assume the visual memory for an object is closely tied to its stored familiar views. The 2D/2D observer is a precise definition of one such view-dependent model. But now note that the statistical efficiencies for novel views are too high. In fact, efficiencies exceeding 100% means that we can exclude from the human-performance model any implementation that verifies matches using remembered templates and rigid image manipulations.

These results show that human recognition uses a much “dumber” view-compensation mechanism than the 3D/2D ideal observer, but a “smarter” one than an independent comparison with stored views. One candidate smarter model would be to allow for 2D affine transformations that include translation, rotation, scale, and skew adjustments in the image domain. Recent work shows that this kind of view compensation gets us closer to human performance, but still fails to account for human ability to recognize novel views (Liu and Kersten, 1998).

4. Conclusions

We have seen how two quite different high-level visual functions, perception of depth and object recognition, can be investigated within the common framework of statistical inference. The perception of depth-from-cast-shadows involves a remarkable synthesis of default prior assumptions on material and lighting, local image cues, and global constraints. We’ve considered just one of more than a dozen sources of information for depth. A quantitative computational model for the perception of spatial layout is an important challenge for future vision research.

A key problem in 3D object recognition is understanding how the brain compensates for variations in viewpoint. By designing a relatively simple visual task for which the optimal inference is computable, one can pit human and ideal observers against each other in the same task. While the computational formulations can be demanding, ideal-observer analysis has the potential to rigorously test well-defined models of human high-level visual functions. Statistical efficiency normalizes performance with respect to the information in the task, with remaining differences diagnostic of processing mechanisms of the visual brain. This research has shown that independent comparisons of images to templates in memory cannot account for human viewpoint compensation, even with some flexibility (via 2D rigid transformations) allowed in the matching process.

For natural images, the information for high-level vision is complex and difficult to model. Our solution to this complexity for depth-from-shadows was a qualitative Bayesian analysis of realistic images. The ideal-observer study of object recognition took a different approach, using a computable but artificial model of uncertainty. A major goal for future research is to develop quantitative ideal observer models for high-level visual functions based on objectively modeled natural image and scene statistics (Zhu, Wu, and Mumford, 1997; Simoncelli, 1997).

NOTES

1. If there is no imaging noise, the density $P(\mathbf{I} - F(\mathbf{S}))$ is a delta function, $\delta(\mathbf{I} - F(\mathbf{S}))$. The delta density is a zero-tolerance filter for wrong scenes—it is zero for scenes that don’t predict the image data and infinitely high for those that do.
2. The intuition behind the equivalence is due to Shannon—that one can achieve efficient communication (in our case, the brain’s decoding of scene properties encrypted in the

image) by seeking shorter image codes, x (in bits), for the more probable scene properties, and longer ones for the less probable ones (i.e., by setting $\text{length}(x) = -\log_2 P(x)$). The total message length is the sum of the length of the code itself plus the length of any discrepancies between the code's description of \mathbf{I} , and the actual \mathbf{I} : $\text{length}(\text{code}, \mathbf{I}) = \text{length}(\text{code}) + \text{length}(\mathbf{I} - F(\text{code}))$. Applying $\log_2()$ to Bayes' formula shows the equivalence: The shortest code, for image \mathbf{I} , will also maximize the posterior probability $p(\mathbf{S}|\mathbf{I})$, which, if the code = \mathbf{S} , would be the most likely scene description.

- More generally, Bayesian decision theory softens the sharp distinction between explicit and generic variables by defining a loss function $L(S, \Sigma)$ which is the penalty for Σ (the estimate of S) when the true scene parameter is S . Then the optimal decision minimizes the risk:

$$R(\Sigma_G, \Sigma_E) = \int L(S_G, \Sigma_G; S_E, \Sigma_E) P(S_E, S_G | I) dS_G dS_E$$

where the subscripts E and G indicate explicit and generic variables. With a loss function, $-\delta(\Sigma_E - S_E)$, where the cost to errors in the generic variable is constant, minimizing risk is equivalent to marginalizing the posterior with respect to the generic variable (i.e., integrating out the generic variable),

$$P(S_E | I) = \int P(S_G, S_E | I) dS_G$$

and choosing the maximum of this posterior density.

- Suppose we have an image measurement, x , which depends on a generic variable, α , and explicit variable z : $x = F(z, \alpha)$. The problem is that we have two unknowns and only one measurement. Assume that the prior, $p(z, \alpha)$, is constant over some domain; then using Bayes' rule, we have $p(z|x) \propto \int p(x|z, \alpha) d\alpha$. Assuming Gaussian measurement noise, we have $p(x|z, \alpha) \propto \int e^{-(x - F(z, \alpha))^2 / 2\sigma^2} d\alpha$. Let $S(\alpha) = (x - F(z, \alpha))^2$. If α_M is a solution of $S'(\alpha_M) = 0$, then the Taylor series expansion of $S(\alpha)$ about α_M is

$$S(\alpha) = (\alpha - \alpha_M)^2 \frac{\partial^2 S}{\partial \alpha^2} \bigg|_{\alpha = \alpha_M} + \dots$$

and

$$p(z|x) \propto \int e^{-(\alpha - \alpha_M)^2 / 2\sigma'^2} d\alpha,$$

where

$$\sigma' = \sigma / 2 \left(\frac{\partial^2 F}{\partial \alpha^2} \right)^2 \bigg|_{\alpha = \alpha_M}$$

This is a standard Gaussian integral, which evaluates to

$$p(z|x) = 1 / \left(\frac{\partial F}{\partial \alpha} \right) \bigg|_{\alpha = \alpha_M}.$$

Thus, more probable values of z result when changes in the generic variable, α , produce small changes in x ($= F(z, \alpha)$).

- Formally, the 3D/2D ideal observer's probability is

$$p_t(\mathbf{I}_k) = \int p(\mathbf{N}_\phi | \mathbf{I} - F_\phi(\mathbf{O})) p(\Phi) d\Phi \\ \propto \int e^{-\|\mathbf{I} - F_\phi(\mathbf{T}_i)\|^2 / \sigma^2} p(\Phi) d\Phi.$$

- The probability, $p_t(\mathbf{I})$, for the 2D/2D observer is given by

$$p_t(\mathbf{I}) = \int_{\phi=0}^{2\pi} [p(\mathbf{I} - R_\phi(\mathbf{T}_i)) p(R_\phi(\mathbf{T}_i))] d\phi$$

where $p(\mathbf{I} | R_\phi(\mathbf{T}_i))$ is the probability that \mathbf{I} was generated by adding noise to template \mathbf{T}_i at 2D rotation angle ϕ . The prior probability, $p(R_\phi(\mathbf{T}_i))$ is constant ($= 1/2\pi$). The actual calculation used was slightly more complicated to allow for uncertainty as to which vertex was first.

- Statistical efficiency is defined as the ratio of the number of data samples the ideal requires to the number the human observer requires for an identical level of performance, e.g., same percent correct (see Liu, Knill, and Kersten, 1995).

26 Perception and Action in the Human Visual System

MELVYN A. GOODALE

ABSTRACT Evidence from studies with neurological patients and normal observers has shown that the control of skilled actions depends on visual processes that are quite independent from those that lead to perception-based knowledge of the world. Moreover, this distinction between vision for perception and vision for action is reflected in the organization of the visual pathways in primate cerebral cortex. Two broad “streams” of projections from primary visual cortex have been identified: a ventral stream projecting to the inferotemporal cortex and a dorsal stream projecting to the posterior parietal cortex. Both streams process information about the structure of objects and about their spatial locations—and both are subject to the modulatory influences of attention. Each stream, however, uses this visual information in different ways. The ventral stream transforms the visual information into perceptual representations that embody the enduring characteristics of objects and their relations. Such representations enable us to identify objects, to attach meaning and significance to them, and to establish their causal relations—operations that are essential for accumulating knowledge about the world. In contrast, the transformations carried out by the dorsal stream deal with moment-to-moment information about the location and disposition of objects with respect to the effector being used and thereby mediate the visual control of skilled actions directed at those objects. Both streams work together in the production of adaptive behavior. The selection of appropriate goal objects and the action to be performed depends on the perceptual machinery of the ventral stream, but the execution of a goal-directed action is carried out by dedicated on-line control systems in the dorsal stream.

When we gaze out of our window, we see a world replete with objects and surfaces, textures and movement, light and shade—a world that has an existence separate from ourselves. Without vision, this rich perception of the world would not exist. For the last 200 years, visual scientists have been trying to find out how our eyes and brain create this percept.

But vision does more than deliver our experience of the world. It also guides our movements through that world. The visual control of movement, however, has until recently been relatively neglected. Indeed, traditional accounts of vision, while acknowledging the role of

vision in the control of movement, have simply regarded it as part of a larger function—that of constructing an internal model of the external world. Even though such accounts might postulate separate “modules” for the processing of different visual features such as motion, color, texture, and form, there is an implicit assumption that in the end vision delivers some sort of unified representation of the external world—a kind of simulacrum of the real thing that serves as the perceptual foundation for all visually driven thought and action.

Over the last ten years, this idea of a monolithic visual system has begun to be challenged. Vision is no longer regarded as a single system delivering a “general-purpose” representation of the external world. Instead, vision is seen as consisting of a number of separate systems in which the input processing of each system has been shaped by the output mechanisms it serves. In particular, it has been suggested that the visual control of actions—from saccadic eye movements to skilled grasping movements of the hand and limb—depend on visual mechanisms that are functionally and neurally separate from those mediating our perception of the world. In this chapter, I will argue that this distinction between vision for action and vision for perception can help us to understand the complex organization of the visual pathways in the human brain. Before examining the intricacies of human vision, however, it might be useful to examine the origins of vision and the role that vision plays in the life of simple organisms.

The evolution of visuomotor control

Vision did not evolve to enable organisms to perceive. It evolved to provide distal control of their movements. Take the case of *Euglena*, a single-cell organism that uses light as a source of energy. *Euglena* has been shown to alter its pattern of swimming as a function of the ambient light levels in different parts of the pond or puddle in which it lives. Such phototactic behavior ensures that the *Euglena* stays longer in regions of its environment where sunlight is available for the manufacture of food (Gould, 1982). To explain this behavior, it is not necessary to

MELVYN A. GOODALE Department of Psychology and Graduate Program in Neuroscience, University of Western Ontario, London, Ontario

argue that the *Euglena* “perceives” the light or even that it has some sort of internal model of the outside world. One simply has to talk about a simple input-output device linking the amount of ambient light to the pattern of locomotion. Of course, a mechanism of this sort, although driven by light, is far less complicated than the visual systems of multicellular organisms. But even in more complex organisms, such as vertebrates, much of vision can be understood entirely in terms of the distal control of movement without reference to experiential perception or any general-purpose representation of the outside world.

As vision evolved in simple vertebrates, visual control systems for different kinds of behavior developed relatively independent neural substrates. Thus, in present-day amphibians, like the frog, there is evidence that visually guided prey-catching and visually guided obstacle avoidance are separately mediated by different pathways from the retina right through to the effector systems producing the movements (Ingle, 1973, 1982, 1991). The visual control of prey-catching depends on circuitry involving retinal projections to the optic tectum while the visual control of locomotion around barriers depends on circuitry involving retinal projections to particular regions of the pretectal nuclei. Each of these retinal targets projects in turn to different premotor nuclei in the brain stem and spinal cord. In fact, accumulating evidence from studies in both frog and toad suggest that there are at least five separate visuomotor *modules*, each responsible for a different kind of visually guided behavior and each having distinct processing routes from input to output (Ingle, 1991; Ewert, 1987). The outputs of these different modules certainly have to be coordinated, but in no sense are they guided by a single general-purpose visual representation in the frog’s brain. [For a discussion of this issue, see Goodale (1996) and Milner and Goodale (1995).]

Although there is evidence that the same kind of visuomotor modularity found in the frog also exists in the mammalian brain (for review, see Goodale, 1996), the very complexity of the day-to-day living in many mammals, particularly in higher primates, demands much more flexible organization of the circuitry. In monkeys (and thus presumably in humans as well), many of the visuomotor circuits that are shared with simpler vertebrates appear to be modulated by more recently evolved control systems in the cerebral cortex (for review, see Milner and Goodale, 1995). This Jacksonian circuitry (Jackson, 1875), in which a layer of cortical control is superimposed on more ancient subcortical networks, makes possible much more adaptive visuomotor behavior. Of course, the basic subcortical circuitry has also changed to some extent and new visuomotor control systems involving both cortical and subcortical

structures have emerged. But even though these complex visuomotor control systems in the primate brain are capable of generating an almost limitless range of visually guided behavior, there is evidence that these visuomotor modules are functionally and neurally separate from those mediating our perception of the world.

The emergence of visual perception

As interactions with the world became more complicated and subtle, direct sensory control of action was not enough. With the emergence of cognitive systems and complex social behavior, a good deal of motor output has become quite arbitrary with respect to sensory input. Many animals, particularly humans and other primates, behave as though their actions are driven by some sort of internal model of the world in which they live. The representational systems that use vision to generate such models or percepts of the world must carry out very different transformations on visual input from the transformations carried out by the visuomotor modules described earlier. For one thing, they are not linked directly to specific motor outputs, but access these outputs via cognitive systems involving memory, semantics, spatial reasoning, planning, and communication. Such higher-order representational systems allow us to perceive a world beyond our bodies, to share that experience with other members of our species, and to plan a vast range of different actions. But even though perception allows us to choose a particular goal, the actual *execution* of an action carried out to fulfil that goal may nevertheless be mediated by dedicated visuomotor modules that are not dissimilar in principle from those found in frogs and toads. In other words, vision in humans and other primates (and perhaps other animals as well) has two distinct but interacting functions: (1) the perception of objects and their relations, which provides a foundation for the organism’s cognitive life; and (2) the control of actions directed at (or with respect to) those objects, in which separate motor outputs are programmed and controlled on-line.

Dorsal and ventral streams

Beyond V1, visual information is conveyed to a bewildering number of extrastriate areas (for review, see Zeki, 1993). Despite the complexity of the interconnections between these different areas, two broad “streams” of projections from V1 have been identified in the macaque monkey brain: a *ventral stream* projecting eventually to the inferotemporal cortex and a *dorsal stream* projecting to the posterior parietal cortex (Ungerleider and Mishkin, 1982). These regions also receive inputs

from a number of other subcortical visual structures, such as the superior colliculus, which sends prominent projections to the dorsal stream (via the thalamus). A schematic diagram of these pathways can be found in figure 26.1. Although some caution must be exercised in generalizing from monkey to human (Crick and Jones, 1993), it seems likely that the visual projections from primary visual cortex to the temporal and parietal lobes in the human brain involve a separation into ventral and dorsal streams similar to that seen in the monkey.

In 1982, Ungerleider and Mishkin argued that the two streams of visual processing play different but complementary roles in the processing of incoming visual information. According to their original account, the ventral stream plays a critical role in the identification and recognition of objects, while the dorsal stream mediates the localization of those same objects. Some have referred to this distinction in visual processing as one between object vision and spatial vision—"what" versus "where." Support for this idea came from work with monkeys. Lesions of inferotemporal cortex in monkeys produced deficits in their ability to discriminate between objects on the basis of their visual features but did not affect their performance on a spatially demanding "landmark" task (Pohl, 1973; Ungerleider and Brody, 1977). Conversely, lesions of the posterior parietal cortex produced deficits in performance on the landmark task but did not affect object discrimination learning (for a critique of these studies, see Goodale, 1995; Milner and Goodale, 1995). Although the evidence for the original Ungerleider–Mishkin proposal initially seemed quite compel-

ling, recent findings from a broad range of studies in both humans and monkeys has forced a reinterpretation of the division of labor between the two streams. As will be detailed in subsequent sections, David Milner and I have offered an account of the two streams that emphasizes the differences in the requirements of the output systems that each stream serves.

Vision for perception and vision for action

David Milner and I have suggested, in contrast to Ungerleider and Mishkin (1982), that both streams process information about object features and about their spatial relations. Each stream, however, uses this visual information in different ways (Goodale and Milner, 1992). In the ventral stream, the transformations focus on the enduring characteristics of objects and their relations, permitting the formation of long-term perceptual representations. Such representations play an essential role in the identification of objects and enable us to classify objects and events, attach meaning and significance to them, and establish their causal relations. As we saw earlier, such operations are essential for accumulating a knowledge base about the world. In contrast, the transformations carried out by the dorsal stream deal with the moment-to-moment information about the location and disposition of objects with respect to the effector being used and thereby mediate the visual control of skilled actions, such as manual prehension, directed at those objects. As such, the dorsal stream can be regarded as a cortical extension of the dedicated visuomotor modules that

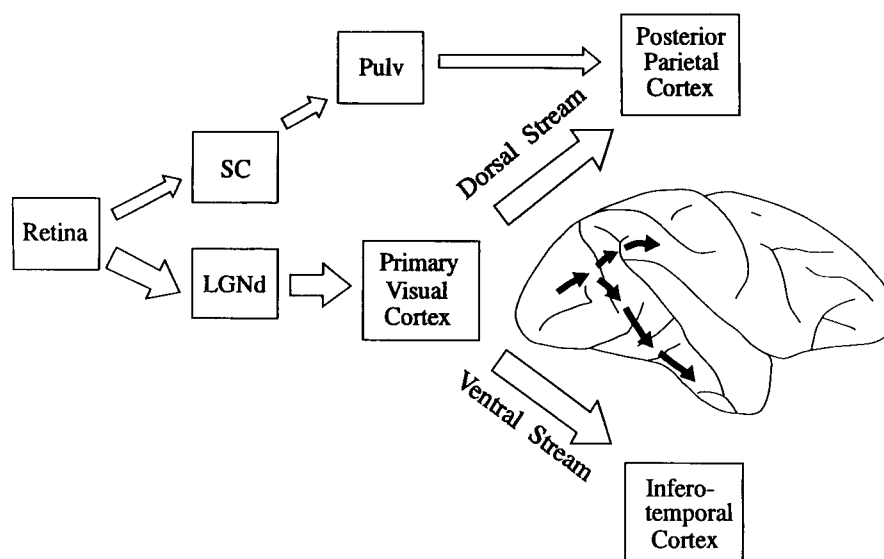

FIGURE 26.1 Major routes whereby retinal input reaches the dorsal and ventral streams. The diagram of the macaque brain (right hemisphere) on the right of the figure shows the approximate routes of the corticocortical projections from primary vi-

sual cortex to the posterior parietal and the inferotemporal cortex, respectively. LGNd: lateral geniculate nucleus, pars dorsalis; Pulv: pulvinar; SC: superior colliculus. (Adapted with permission from Goodale et al., 1994.)

mediate visually guided movements in all vertebrates. The perceptual representations constructed by the ventral stream interact with various high-level cognitive mechanisms and enable an organism to select a particular course of action with respect to objects in the world while the visuomotor networks in the dorsal stream (and associated cortical and subcortical pathways) are responsible for the programming and on-line control of the particular movements that action entails.

This division of labor between the two cortical visual pathways requires that different transformations be carried out on incoming visual information. Consider first the task of the perceptual system in the ventral stream. To generate long-term representations of objects and their relations, perceptual mechanisms must be “object-based”; i.e., constancies of size, shape, color, lightness, and relative location need to be maintained across different viewing conditions. Some of these mechanisms might use a network of viewer-centered representations of the same object (e.g., Bülthoff and Edelman, 1992); others might use an array of canonical representations (e.g., Palmer, Rosch, and Chase, 1981); still others might be truly “object-centered” (Marr, 1982). But whatever the particular coding might be, it is the identity of the object, not its disposition with respect to the observer, that is of primary concern to the perceptual system. This is not the case for the visuomotor mechanisms in the dorsal stream and other related structures that support actions directed at that object. In this case, the underlying visuomotor transformations have to be viewer-centered; in other words, both the location of the object and its disposition and motion must be encoded relative to the observer in egocentric coordinates, that is in retinocentric, head-centered, torso-centered, or shoulder-centered coordinates. (One constancy that must operate, however, is object size; in order to scale the grasp during prehension, the underlying visuomotor mechanisms must be able to compute the real size of the object independent of its distance from the observer.) Finally, because the position and disposition of a goal object in the action space of an observer is rarely constant, such computations must take place *de novo* every time an action occurs (for a discussion of this issue, see Goodale, Jakobson, and Keillor, 1994). In other words, the action systems of the dorsal stream do most of their work on-line; only the perception systems of the ventral stream can afford to work off-line. To summarize then, while similar (but not identical) visual information about object shape, size, local orientation, and location is available to both systems, the transformational algorithms that are applied to these inputs are uniquely tailored to the function of each system. According to our proposal, it is the nature of the functional requirements of perception and ac-

tion that lies at the root of the division of labor in the ventral and dorsal visual projection systems of the primate cerebral cortex.

Neuropsychological evidence for perception and action streams

In the intact brain, the two streams of processing work together in a seamless and integrated fashion. Nevertheless, by studying individuals who have sustained brain damage that spares one of these systems but not the other, it is possible to get a glimpse into how each stream transforms incoming visual information.

PERCEPTION WITHOUT ACTION It has been known for a long time that patients with lesions in the superior regions of the posterior parietal cortex can have problems using vision to direct a grasp or aiming movement toward the correct location of a visual target placed in different positions in the visual field, particularly the peripheral visual field. This particular deficit is often described as *optic ataxia* (Bálint, 1909). But the failure to locate an object with the hand should not be construed as a problem in spatial vision; many of these patients can, for example, describe the relative position of the object in space quite accurately, even though they cannot direct their hand toward it (Jeannerod, 1988; Perenin and Vighetto, 1988). Moreover, sometimes the deficit will be seen in one hand but not the other. Problems in the visual control of locomotion and the production of voluntary saccades have also been observed following damage to the posterior parietal region (for review, see Milner and Goodale, 1995). It should be pointed out, of course, that these patients typically have no difficulty using input from other sensory systems, such as proprioception or audition, to guide their movements. Their deficit is neither “purely” visual nor “purely” motor but is instead a visuomotor deficit.

Some of these patients are unable to use visual information to rotate their hands or scale the opening of their fingers when reaching out to pick up an object, even though they have no difficulty describing the size or orientation of objects in that part of the visual field (Jakobson et al., 1991; Jeannerod, 1988; Jeannerod, Decety, and Michel, 1994; Goodale et al., 1993; Perenin and Vighetto, 1988). Similarly, as figure 26.2 illustrates, patients with damage to this region can also show deficits in the selection of stable grasp points on the surface of objects of varying shape (Goodale et al., 1994). These results show that the visuomotor disturbances accompanying damage to the posterior parietal cortex need not be limited to deficits in the spatial control of movements but can extend to object features such as size, shape, and

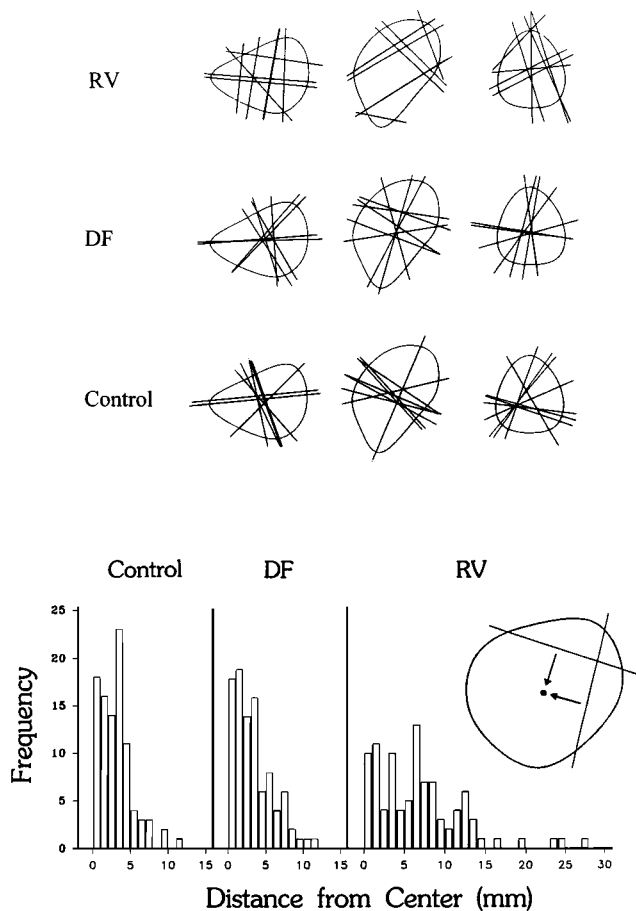

FIGURE 26.2 The diagram at the top of this figure shows the “grasp lines” (joining points where the thumb and index finger first made contact with the shape) selected by the optic ataxia patient (RV), the visual agnosic patient (DF), and the control subject (SH) when picking up three of the twelve shapes used in the study. The four different orientations in which each shape was presented have been rotated so that they are aligned. Notice the similarity between DF’s grasp lines and those of the control subject, and how their grasp lines differ from those of RV who often chooses very unstable grasp points. The frequency distributions below illustrate the distance between the grasp lines and the center of mass of the shape for DF, RV, and the control subject (SH) for all twelve shapes. The inset shows how these distances were computed. Notice again that whereas DF and SH’s grasp lines tended to pass through or close to the center of mass of the shape, this was not the case for RV. (Adapted with permission from Goodale et al., 1994.)

orientation. Nevertheless, it is worth emphasizing that the deficits are visuomotor in nature not perceptual; the patients have no trouble discriminating between objects of different size or shape or between objects placed in different orientations.

The various visuomotor deficits that have been described in patients with damage to the posterior parietal region are quite dissociable from one another. Some patients are unable to use visual information to control

their hand postures but have no difficulty controlling the direction of their grasp; others show the reverse pattern. Some patients are unable to foveate a target object, but have no difficulty directing a well-formed grasp in its direction; others may show no evidence of an oculomotor deficit but be unable to guide their hand toward an object under visual control. Indeed, depending upon the size and locus of the lesion, a patient can demonstrate any combination of these visuomotor deficits (for review, see Milner and Goodale, 1995). Different subregions of the posterior parietal cortex, it appears, are critical for the visual control of different motor outputs. A particular motor act, such as reaching out and grasping an object, presumably would engage visuomotor mechanisms in a number of these different areas, including those involved in the control of saccades, visual pursuit, reaching with the limb, and grasping movements of the hands and fingers (for a discussion of the different components of manual prehension, see Jeannerod, 1988). Just how such mechanisms are coordinated is not well understood—although some models have been proposed (e.g., Hoff and Arbib, 1992). In any case, it is clear that the visual control of each of the constituent actions will require different sensorimotor coordinate transformations and there have been some attempts to specify how the posterior parietal cortex might mediate such transformations (e.g., Flanders, Tillery, and Soechting, 1992; Stein, 1992). But again, even though patients with damage to the posterior parietal region may show a variety of different visuomotor deficits, they can often describe (and hence presumably perceive) the intrinsic visual features and the location of the very object they are unable to grasp, foveate, and/or walk toward.

ACTION WITHOUT PERCEPTION The fact that patients with damage to posterior parietal cortex can perceive objects but cannot grasp them provides one piece of evidence that there are separate neural substrates for perception and action in the human brain. It also suggests that the superior regions of the posterior parietal cortex, the human homolog of the monkey dorsal stream, is critical for the visual control of action. But even more compelling evidence for separate visual systems for perception and action comes from patients who show the opposite pattern of deficits and spared visual abilities. Take the case of DF, for example.

DF is a woman, now in her early 40s, who had the misfortune at age 34 to suffer irreversible brain damage as a result of near-asphyxiation by carbon monoxide. When she regained consciousness, it was apparent that DF’s visual system had been badly damaged by the anoxia. She was unable to recognize the faces of her relatives and friends or identify the visual form of common

objects. In fact, she could not even tell the difference between simple geometric shapes such as a square and a triangle. At the same time, she had no difficulty recognizing people from their voices or identifying objects placed in her hands; her perceptual problems appeared to be exclusively visual. Even today, more than ten years after the accident, she remains quite unable to identify objects or drawings on the basis of their visual form.

The damage in DF's brain is quite diffuse, a common pattern in cases of anoxia. Nevertheless, certain areas of her brain, especially those in the posterior region of her cerebral cortex, appear to be more severely damaged than others. Magnetic resonance imaging carried out just over a year after her accident showed that the ventrolateral regions of her occipital lobe are particularly compromised. Primary visual cortex, however, appears to be largely spared in DF (for details, see Milner et al., 1991).

DF's perceptual problems are not simply a case of being unable to associate a visual stimulus with meaningful semantic information. For example, while it is true that she cannot find the right name or semantic association for the objects depicted in the simple line drawings illustrated in the left-hand column of figure 26.3, she is also completely unable to draw what she sees when she looks at the line drawing. Moreover, her inability to copy drawings is not due to a problem in controlling the movements of the pen or pencil. When she is asked to

draw a particular object from memory, she is able to do so reasonably well, as the drawings on the right-hand side of figure 26.3 illustrate.

Nor is DF's inability to perceive the shape and form of objects in the world due to deficits in basic sensory processing (Milner et al., 1991). She remains quite capable of identifying colors, for example. In addition, perimetric testing carried out quite early after her accident showed that she could detect luminance-defined targets at least as far out as 30° into the visual periphery. Her spatial contrast sensitivity was also normal above 5 Hz and was only moderately impaired at lower spatial frequencies. Of course, even though she could detect the presence of the spatial frequency gratings in these tests, she could not report their orientation. In fact, DF has great problems describing or discriminating the orientation and form of any visual contour, no matter how that contour is defined. Thus, she cannot identify shapes whose contours are defined by differences in luminance or color, or by differences in the direction of motion or the plane of depth. Nor can she recognize shapes that are defined by the similarity or proximity of individual elements of the visual array. Nevertheless, information about the spatial distribution of the visual array appeared to reach her primary visual cortex. Thus, when she was shown a high-contrast reversing checkerboard pattern in an electrophysiological assessment carried out just after the accident, the initial components of the evoked response, such as the P100, appeared to be quite normal, suggesting that her primary visual cortex was working normally. In short, DF's deficit seems to be "perceptual" rather than "sensory" in nature. She simply cannot perceive shapes and forms—even though the early stages of her visual system would appear to have access to the requisite low-level sensory information.

What is most remarkable about DF, however, is that despite her profound deficits in form vision, she is able to use visual information about the size, shape, and orientation of objects to control a broad range of visually guided movements. DF will reach out and grasp your hand if you offer it when you first meet her. She is equally adept at reaching out for a door handle—even in an unfamiliar environment. She can walk unassisted across a room or patio, stepping easily over low obstacles and walking around higher ones. Even more amazing is the fact that she can reach out and grasp an object placed in front of her with considerable accuracy and confidence—despite the fact that moments before she was quite unable to identify or describe that same object.

These dissociations between DF's perceptual abilities and her ability to use visual information to control skilled movements are also evident in formal testing (Goodale et al., 1991). For example, when she is pre-

FIGURE 26.3 Patient DF's attempts to draw from models and from memory. DF was unable to identify the line drawings of an apple and an open book shown on the left. In addition, her copies were very poor. Note that she did incorporate some elements of the line drawing (e.g., the dots indicating the text in the book) into her copy. When she was asked on another occasion to draw an apple or an open book from memory, she produced a respectable representation of both items (right-hand column). When she was later shown her own drawings, she had no idea what they were. (Adapted with permission of Elsevier Science from Servos, Goodale, and Humphrey, 1993.)

sented with a series of rectangular blocks that vary in their dimensions but not in their overall surface area, she is unable to say whether or not any two of these blocks are the same or different. Even when a single block is placed in front of her, she is unable to indicate how wide the block is by opening her index finger and thumb a matching amount. Nevertheless, when she reaches out to pick up the block using a precision grip, the opening between her index finger and thumb is scaled in flight to the width of the object, just as it is in subjects with normal vision.

A similar dissociation can be seen in DF's processing of the orientation of objects (Goodale et al., 1991). Thus, even though she cannot discriminate between objects placed in different orientations on a table in front of her, she can rotate her hand in the correct orientation when she reaches out to grasp one of the objects. When presented with a large slot in a vertical surface, she is unable to rotate a hand-held card to match the orientation of that slot (see figure 26.4). But again, when she attempts to insert the hand-held card into the slot, she rotates the card in the appropriate way as she moves it toward the slot (figure 26.4). She can also use information about the shape of an object to locate stable grasp points on its surface when she picks it up (Goodale et al., 1994). Thus, when grasping an object like those illustrated in figure 26.2, DF will place her finger and thumb so that a line joining the opposing points of contact passes through the object's center of mass. And, unlike the patient with posterior parietal damage whose performance is also illustrated in figure 26.2, DF chooses points on the object's boundary where her fingers are the least likely to slip—such as points of high convexity or concavity—just as the control subject with normal vision does. Needless to say, DF is quite unable to tell these objects apart in a same-different discrimination. In short, DF can use visual information about the size, orientation, and shape of objects to program and control her goal-directed movements even though she has no meaningful perception of those object features.

As I mentioned earlier, these spared visuomotor skills are not limited to reaching and grasping movements; DF can also walk around quite well under visual control. When she was tested more formally, we found that she is able to negotiate obstacles during locomotion as well as control subjects (Patla and Goodale, 1997). Thus, when obstacles of different heights were randomly placed in her path on different trials, she stepped over these obstacles quite efficiently and the elevation of her toe increased linearly as a function of obstacle height, just as it does in neurologically intact individuals. Yet when she was asked to give verbal estimates of the height of the obstacles, the slope of the line relating esti-

FIGURE 26.4 Top: Apparatus that was used to test sensitivity to orientation in patient DF. The slot could be placed in any one of a number of orientations around the clock. Subjects were required either to rotate a hand-held card to match the orientation of the slot or to "post" the card into the slot as shown in this figure. Bottom: Polar plots of the orientation of the hand-held card on the perceptual matching task and the visuomotor posting task for DF and an age-matched control subject. The correct orientation on each trial has been rotated to vertical. Note that although DF was unable to match the orientation of the card to that of the slot in the perceptual matching card, she did rotate the card to the correct orientation as she attempted to insert it into the slot on the posting task. (Adapted with permission from Goodale, 1995.)

mated and actual obstacle height was much shallower in her case than it was in normal subjects. Similar dissociations between perceptual judgments about the pitch of the visual field and its effect on eye position have also been observed in DF (Servos, Matin, and Goodale, 1995).

There is also evidence for a dissociation between the perception of spatial relations and the use of egocentric spatial information for motor control in DF. When asked, for example, to copy a simple array of colored tokens laid out on a surface by using a similar set of tokens, she generates a rather poor copy. Yet at the same time, when asked to point in turn to each of the colored tokens in the original array, her performance is quite normal (Murphy, Carey, and Goodale, 1998). In other words, despite the fact that she has excellent egocentric coding of the spatial position of objects, her perceptual representation of the relative position of those objects (sometimes called allocentric coding) is clearly abnormal.

To summarize: Even though DF's brain damage has left her unable to perceive the size, shape, and orientation of objects, her visuomotor outputs remain quite sensitive to these same object features. There appears to have been an interruption in the normal flow of shape and contour information into her perceptual system without affecting the processing of shape and contour information by her visuomotor control systems. But where is the damage in DF's brain? If, as was suggested earlier, the perception of objects and events is mediated by the ventral stream of visual projections to inferotemporal cortex, DF should show evidence for damage relatively early in this pathway. Certainly, the pattern of damage revealed by the MRI is consistent with this interpretation; the major focus of cortical damage is in the ventrolateral region of the occipital cortex, an area thought to be part of the human homolog of the ventral stream. At the same time, her primary visual cortex, which provides input for both the dorsal and ventral streams, appears to be largely intact. Thus, although input from primary visual cortex to the ventral stream has been compromised in DF, input from this structure to the dorsal stream appears to be essentially intact. In addition, the dorsal stream, unlike the ventral stream, also receives important visual input from the superior colliculus via the pulvinar, a nucleus in the thalamus (see figure 26.1). Indeed, recent work by Perenin and Rossetti (1996) suggests that this collicular-pulvinar route to the dorsal stream may be able to support object-directed grasping movements even without input from V1. They tested a patient who was completely blind (by conventional testing) in one-half of his visual field following a medial occipital lesion that included all of V1. The patient could not see any objects in his blind field. Nevertheless, when he was persuaded to reach out and grasp objects placed in his blind field, he showed some evidence of sensitivity to the size and orientation of objects. Thus, there are at least two routes whereby information could reach the dorsal stream in DF: from the superior

colliculus (via the pulvinar) and from the lateral geniculate nucleus (via primary visual cortex). Either or both of these pathways could be continuing to mediate well-formed visuomotor responses in DF.

One must be cautious, however, about drawing strong conclusions about anatomy and pathways from patients like DF. Her deficits arose not from a discrete lesion, but from anoxia. As a consequence, the brain damage in DF, while localized to some extent, is much more diffuse than it would be in a patient with a stroke or tumor. Thus, while the striking dissociation between perceptual and visuomotor abilities in DF can be mapped onto the distinction between the ventral and dorsal streams of visual processing that David Milner and I proposed (Goodale and Milner, 1992), that mapping can be only tentative. The proposal is strengthened, however, by observations in patients like those described in the previous section whose pattern of deficits is complementary to DF's and whose brain damage can be confidently localized to the dorsal stream.

In summary, the neuropsychological findings can be accommodated quite well by the proposal that the division of labor between the ventral and dorsal streams of visual processing is based on the distinction between visuomotor control and the more visuo-cognitive functions of vision. Moreover, as we shall see in the next section, this new way of looking at the organization of the visual system is also consistent with the story that is emerging from anatomical, neurophysiological, and behavioral work in the monkey.

Evidence from monkey studies

A broad range of different studies on the dorsal and ventral streams in the monkey lend considerable support to the distinction outlined above (for a detailed account of this work, see Milner and Goodale, 1995). For example, monkeys with lesions of inferotemporal cortex, who show profound deficits in object recognition, are nevertheless as capable as a normal animal at picking up small objects (Klüver and Bucy, 1939), at catching flying insects (Pribram, 1967), and at orienting their fingers to extract morsels of food embedded in small slots (Buchbinder et al., 1980). Like DF, these monkeys are unable to discriminate between objects on the basis of the same visual features that they apparently use to direct their grasping movements. In addition to the lesion studies, there is a long history of electrophysiological work showing that cells in inferotemporal cortex and neighboring regions of the superior temporal sulcus are tuned to specific objects and object features—and some of them maintain their selectivity irrespective of viewpoint, retinal image size, and even color (for review, see Milner

and Goodale, 1995). Moreover, the responses of these cells are not affected by the animal's motor behavior but are instead sensitive to the reinforcement history and significance of the visual stimuli that drive them. It has been suggested that cells in this region might play a role in comparing current visual inputs with internal representations of recalled images (e.g., Eskandar, Richmond, and Optican, 1992), which are themselves presumably stored in other regions, such as neighboring regions of the medial temporal lobe and related limbic areas (Fahy, Riches, and Brown, 1993; Nishijo et al., 1993). In fact, sensitivity to particular objects can be created in ensembles of cells in inferotemporal cortex simply by training the animals to discriminate between different objects (Logothetis, Pauls, and Poggio, 1995). These and other studies too numerous to cite here lend considerable support to the suggestion that the object-based descriptions provided by the ventral stream form the basic raw material for recognition memory and other long-term representations of the visual world.

In sharp contrast to the activity of cells in the ventral stream, the responses of cells in the dorsal stream are greatly dependent on the concurrent motor behavior of the animal. Thus, separate subsets of visual cells in the posterior parietal cortex, the major terminal zone for the dorsal stream, have been shown to be implicated in visual fixation, pursuit and saccadic eye movements, visually guided reaching, and the manipulation of objects (Hyvärinen and Poranen, 1974; Mountcastle et al., 1975). In reviewing these studies, Andersen (1987) has pointed out that most neurons in these areas "exhibit both sensory-related and movement-related activity." Moreover, the motor modulation is quite specific. Recent work in Andersen's laboratory, for example, has shown that visual cells in the posterior parietal cortex that code the location of a target for a saccadic eye movement are quite separate from cells in this region that code the location for a manual aiming movement to the same target (Snyder, Batista, and Andersen, 1997). In other experiments (Taira et al., 1990), cells in the posterior parietal region that fire when the monkey manipulates an object have also been shown to be sensitive to the intrinsic object features, such as size and orientation, that determine the posture of the hand and fingers during a grasping movement. Lesions in this region of the posterior parietal cortex produce deficits in the visual control of reaching and grasping similar in many respects to those seen in humans following damage to the homologous region (e.g., Ettlinger, 1977). The posterior parietal cortex is also intimately linked with premotor cortex, the superior colliculus, and pontine nuclei—brain areas that have also been implicated in various aspects of the visual control of eye, limb, and body movements (for review, see Goodale,

1996). In short, the networks in the dorsal stream have the functional properties and interconnections that one might expect to see in a system concerned with the moment-to-moment control of visually guided actions. [Of necessity, this review of the monkey literature is far from complete. Interested readers are directed to Milner and Goodale (1995) and Jeannerod (1997).]

Perception and action in the normal observer

Although the evidence from neurological patients discussed earlier points to a clear dissociation between the visual pathways supporting perception and action, one might also expect to see evidence for such a dissociation in neurologically intact individuals. In other words, the visual information that is used to calibrate and control a skilled motor act directed at an object might not always match the perceptual judgments that are made about that object. After all, the control of skilled actions imposes requirements on visual processing that are different from those demanded of the mechanisms supporting visual recognition. Efficient grasping, for example, demands rapid and accurate computation of the size, shape, orientation, and location of the object; and the required computations for action must be organized within egocentric frames of reference. For example, while we might *perceive* that one object is larger or closer than another, such relative judgments of size and distance are not enough to calibrate the grasping movement directed at that object; to grasp the object accurately, it is necessary to know its *exact* size and distance.

Although there are numerous examples of such dissociations in the literature, particularly with respect to the spatial location of visual stimuli (for review, see Goodale and Haffenden, 1998), some of the most compelling demonstrations have involved the use of pictorial illusions. Take the Ebbinghaus illusion for example. In this familiar illusion, which is illustrated in figure 26.5, two target circles of equal size, each surrounded by a circular array of either smaller or larger circles, are presented side by side. Subjects typically report that the target circle surrounded by the array of smaller circles appears larger than the one surrounded by the array of larger circles, presumably because of the difference in the contrast in size between the target circles and the surrounding circles. In another version of the illusion, also illustrated in figure 26.5, the target circles can be made to appear identical in size by increasing the actual size of the target circle surrounded by the larger circles.

Although our perceptual judgments are clearly affected by these manipulations of the stimulus array, there is good reason to believe that the calibration of

FIGURE 26.5 The Ebbinghaus illusion. Panel a shows the standard version of the illusion in which physically identical target circles appear perceptually different. Most people judge the target circle surrounded by the annulus of smaller circles to be larger than the other target circle. Panel b shows a version of the illusion in which the target circle surrounded by the annulus of larger circles has been made physically larger than the other target, compensating for the effect of the illusion. Most people now see the two target circles as equivalent in size. (Adapted with permission from Aglioti, DeSouza, and Goodale, 1995.)

size-dependent motor outputs, such as grip aperture during grasping, would not be. When we reach out to pick up an object, we must compute its real size if we are to pick it up efficiently. As was mentioned earlier, it is not enough to know that it is larger or smaller than surrounding objects. One might expect, therefore, that grip scaling would be insensitive to size-contrast illusions such as the Ebbinghaus illusion. Such a result was recently found in two experiments that used a three-dimensional version of the illusion in which two thin “poker-chip” disks were arranged as pairs on a standard Ebbinghaus annular circle display (Aglioti, DeSouza, and Goodale, 1995; Haffenden and Goodale, 1998). Trials in which the two disks appeared perceptually identical but were physically different in size were randomly alternated with trials in which the disks appeared perceptually different but were physically identical. Even though subjects showed robust perceptual illusions—even in a matching task in which they opened their index finger and thumb to match the perceived diameter of one of the disks—their grip aperture was correlated with the real size of the disk when they reached out to pick it up (see figure 26.6).

But why should perception be so susceptible to this illusion while the calibration of grasp is not? The mecha-

nisms underlying the size-contrast illusion are not well understood. It is possible that it arises from a straightforward relative size judgment, whereby an object that is smaller than its immediate neighbors is assumed to be smaller than a similar object that is larger than its immediate neighbors. It is also possible that some sort of image-distance equation is contributing to the illusion in which the array of smaller circles is assumed to be more distant than the array of larger circles. As a consequence, the target circle within the array of smaller circles will also be perceived as more distant (and therefore larger) than the target circle of equivalent retinal image size within the array of larger circles. In other words, the illusion may be simply a consequence of the perceptual system’s attempt to make size constancy judgments on the basis of an analysis of the entire visual array (Coren, 1971; Gregory, 1963).

Mechanisms such as these, in which the relations between objects in the visual array play a crucial role in scene interpretation, are clearly central to perception. As we look out across a landscape, we cannot help but see some objects as larger or closer than others. In contrast, the execution of a goal-directed act such as grasping depends on computations that are centered on the target itself and must take into account the actual size and distance of that target—and transform that information into the coordinates of the effectors that carry out the actions. The relative size and distance between the target object and others in the scene are of no consequence to the computations mediating action.

The integration of perception and action

Although I have been emphasizing the fact that the dorsal action stream and the ventral perception stream are anatomically and functionally distinct, the two streams must work together in everyday life. Indeed, an argument can be made that the two streams play complementary roles in the production of adaptive behavior.

A useful metaphor for understanding the different contributions of the dorsal and ventral stream to visually guided behavior can be found in robotic engineering. That metaphor is *teleassistance* (Pook and Ballard, 1996). In teleassistance, a human operator identifies the goal and then uses a symbolic language to communicate with a semi-autonomous robot that actually performs the required motor act on the identified goal object. Teleassistance is much more flexible than completely autonomous robotic control, which is limited to the working environment for which it has been programmed and cannot cope easily with novel events. Teleassistance is also more efficient than teleoperation, in which a human operator simply controls the move-

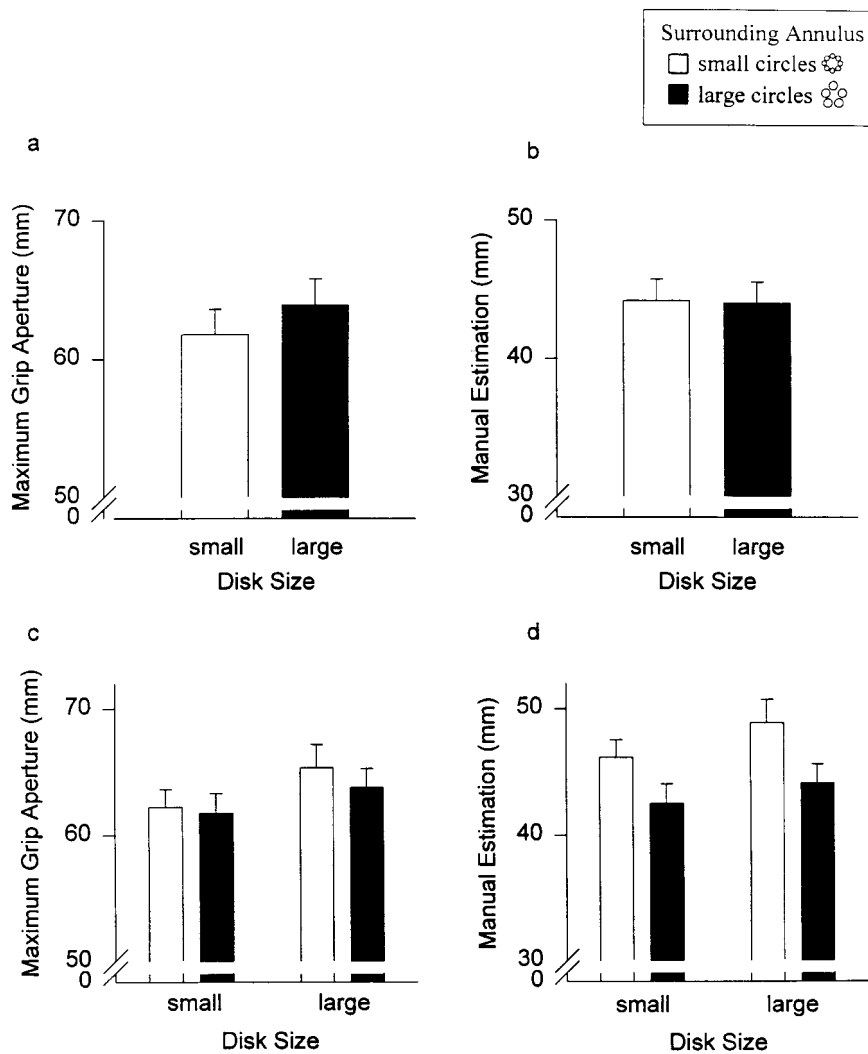

FIGURE 26.6 Calibration of the grasp (on left) and manual estimations (on right) for disks surrounded by the illusory annuli: (a and b) Perceptually identical conditions; (c and d) perceptually different conditions. The difference between the maximum grip aperture achieved during a grasping movement was significantly greater for large disks than the maximum grip aperture for small disks independent of whether or not the subject perceived the disks to be the same or different sizes ($p < .05$). Manual estimations were influenced by the illusory display. The difference between manual estimations of the large and small disks in the perceptually identical condition was not

significant ($p > .05$). Perceptually different, but physically identical disk pairs produced significantly different manual estimations. The small disk surrounded by the small circle annulus was estimated to be larger than the small disk surrounded by the large circle annulus ($p < .01$). Manual estimations of the pair of large disks produced a similar result. The large disk surrounded by the small circle annulus was estimated to be larger than the large disk surrounded by the large circle annulus ($p < .05$). Error bars indicate the standard error of the mean averaged within each condition for all subjects. (Adapted with permission from Haffenden and Goodale, 1998.)

ment of a manipulandum at a distance. As Pook and Ballard (1996) have demonstrated, teleoperation (i.e., the human operator) cannot cope with sudden changes in scale or the delay between action and feedback from that action. In short, teleassistance combines the flexibility of teleoperation with the precision of autonomous routines.

The interaction between the ventral and dorsal streams is an excellent example of the principle of teleassistance, but in this case instantiated in biology. The

perceptual-cognitive systems in the ventral stream, like the human operator in teleassistance, identify different objects in the scene—using a representational system that is rich and detailed but not metrically precise. When a particular goal object has been flagged, dedicated visuomotor networks in the dorsal stream (in conjunction with related circuits in premotor cortex, basal ganglia, and brain stem) are activated to perform the desired motor act. Thus, the networks in the dorsal stream, with their precise egocentric coding of the location, size,

orientation, and shape of the goal object, are like the robotic component of teleassistance. Thus, both systems are required for purposive behavior—one system to select the goal object from the visual array, the other to carry out the required metrical computations for the goal-directed action. One of the most important questions yet to be addressed is how the two streams communicate with one another.

27 Visual Associative Long-Term Memory: Encoding and Retrieval in Inferotemporal Cortex of the Primate

YASUSHI MIYASHITA

ABSTRACT The neural mechanisms that enable manipulation of visual images in mind are examined. To provide a solid neurophysiological basis for the studies devoted to visual imagery, an animal model was devised. Macaque monkeys were trained to memorize visual objects in associative memory and to retrieve the active internal representation (“image”) of the objects from long-term storage according to an associative cue. A color switch was used to control the need for image generation and its initiation time, independently of the cue itself. In the inferotemporal cortex, we found a group of neurons whose activity represented the active image of a specific object in mind. The neural representation could be recalled or suppressed according to the need of image generation. How, then, is the association between the cue and the image represented and created? By using an object–object association task, we demonstrate that inferotemporal neurons can encode arbitrarily defined associative relations between objects. We then found that the interaction between the medial temporal lobe and inferotemporal cortex plays an essential role in the encoding process. This interaction was analyzed by electrophysiological single unit recording, combined with neurotoxic lesions and molecular biological methods. These studies opened a new approach for understanding the neural mechanisms of memory encoding and retrieval.

Create an image of the Pantheon in your mind. Can you count the columns that support its pediment?

—E. A. C. Alain (1926)

Our ability to “see with the mind’s eye” has been of interest to philosophers and scientists for a long time. When the nature of the reflective consciousness was investigated by reflection, it was often asked whether [strong] “image” and [weak] “perception” are distinguishable in both psychological and epistemological dimensions (Sartre, 1938). Consider the Pantheon and its columns, as shown in figure 27.1 (see color plate 10). Recalling those columns is a well known litmus test for

such a distinction. Mental images are not actual pictures in the brain; obviously, we cannot assume a homunculus in the brain who looks at the images. Nevertheless, the research on imagery is challenging since imagery is one of the first higher cognitive abilities that is firmly rooted in the brain. And it is clearly an important topic, since understanding this ability would provide some constraints on the neural basis of consciousness.

Today many approaches (mostly neuroimaging, as well as electrophysiological, psychophysical, and neuropsychological approaches) are being used to ask where and how pictorial representations of objects, scenes, and living beings are generated, stored, and maintained in the brain (Roland, 1993; Kosslyn, 1994; Miyashita, 1995). Even the question of to what degree the processes involved in visual perception and imagery share a common neural substrate has partially been answered. Here we attempt to provide a solid neurophysiological basis for those studies by using an animal model. In our visual memory tasks, monkeys were asked to encode visual objects in associative long-term memory and to retrieve internal representations of the objects from long-term storage according to an appropriate cue. The monkeys can recall the internal representation even without direct sensory stimulation (Hasegawa et al., 1998). Here we note that the nature of the internal representation that lies in the deepest structure for imagery or image generation has been long debated (Pylyshyn, 1981; Kosslyn, 1994); however, recent neuroscience investigations strongly suggest contributions of depictive representation in both humans and monkeys (Kosslyn, 1994; Miyashita, 1995). In humans, especially when verbal instruction triggers the image generation, propositional representation may also contribute to that generation (Pylyshyn, 1981). Therefore, the word “image,” as used in this chapter, indicates a depictive internal representation that lies under the goal-directed behavior in the memory tasks of monkeys.

YASUSHI MIYASHITA Department of Physiology, The University of Tokyo School of Medicine, Hongo, Tokyo; Laboratory of Cognitive Neuroscience, National Institute for Physiological Sciences, Okazaki; Mind Articulation Project, ICORP, Japan Science and Technology Corporation, Yushima, Tokyo

FIGURE 27.1 Visual perception mainly relies on the forward, bottom-up flow of information. Image retrieval or imagery experience, in contrast, highlights the backward projections as an anatomical substrate of top-down mental operations. If an imagery task requires reconstruction of the detailed local geometry of the image (as in counting the columns in a memory of

the Pantheon), backward signals from higher-order representations might reach topographically organized visual areas. This cartoon does not indicate that mental images are actual pictures in the brain; obviously, we cannot assume any homunculus in the brain who looks at the images. (Adapted from Miyashita, 1995; artwork by K. Sutliff.)

We start from a neuronal correlate of image generation in monkey inferotemporal cortex. We demonstrate that single neurons become active when the monkey generates from its long-term memory store the image that is instructed by a previous cue stimulus (Miyashita et al., 1998; Naya, Sakai, and Miyashita, 1996). Neurons in inferotemporal cortex can respond to such a prospective object, as well as a retrospective object in memory or a visible object (Miyashita, 1988, 1993). Then we explore the question of where such a prospective activation of an object's image can originate. By using the object-object association task for monkeys, we demonstrate that inferotemporal neurons can encode associative relations between objects and can provide a kind of semantic network among objects (Miyashita, 1993). We found that, in the process of encoding of visual objects, the interaction between the medial temporal lobe and inferotemporal cortex plays an essential role. We analyze this interaction by combination of electrophysiological single unit recording, neurotoxic lesions, and molecular biological methods (Miyashita et al., 1998; Okuno and Miyashita, 1996). These studies clarified how the associative long-term memory of objects is en-

coded and how the prospective activation of an object's image emerges. Comparison with the human imagery system is also discussed.

Neuronal representation of visual long-term memory

Along the occipitotemporal visual pathway from the primary visual cortex (figure 27.1), the physical properties of a visual object are analyzed in the multiple subdivisions of the prestriate and posterior temporal cortices, and the inferotemporal cortex synthesizes the analyzed attributes into a unique configuration (Mishkin, 1982; Van Essen et al., 1992; Miyashita, 1993). The inferotemporal cortex has been proposed to be the memory storehouse for object vision on the basis of behavioral experiments (Mishkin, 1982; Squire, 1987). But how are the memories of objects represented among neuronal networks in the inferotemporal cortex?

Most of our long-term memories of episodes and semantic knowledge are organized so that we can retrieve them by association. We propose that visual memory is organized by the same principle, encoding

the forms of objects as structured bundles of associations between elementary views of objects (Miyashita, Date, and Okuno, 1993). We obtained evidence for the associative mechanism by training monkeys to memorize artificial associative relations among visual patterns, then examining whether picture-selective activities of inferotemporal neurons encode the stimulus–stimulus association imposed in the learning (Miyashita, 1988, 1993). One example of such studies used the pair-association (PA) learning task (Sakai and Miyashita, 1991; Higuchi and Miyashita, 1996) by modifying a human declarative memory task (Wechsler, 1987). The results provided strong evidence that inferotemporal neurons acquire stimulus selectivity through associative learning and that the selectivity reflects a stimulus–stimulus association among geometrically different forms. But in this chapter we start from discoveries of retrieval-related neurons in inferotemporal cortex, since the pair-association task requires both encoding and retrieval of the object image.

Neuronal correlate of mental imagery in inferotemporal cortex

In our pair-association task for monkeys, meaningless computer-generated colored pictures were sorted randomly into pairs (G1/B1 to G12/B12), each pair containing a green picture and a blue picture (figure 27.2; see color plate 11). The combination of the paired associates cannot be predicted without memorizing them beforehand, and macaque monkeys (*Macaca fuscata*) were trained to memorize these pairs. In each trial of the task, a cue stimulus was presented, and then the monkey was rewarded when he chose the paired associate of the cue. It should be noted that this task is essentially a memory *recall* task, which demands activation of internal representation of a picture from long-term memory.

In an earlier experiment with monochromatic visual stimuli (Sakai and Miyashita, 1991), we found an interesting category of neurons—*pair-recall neurons*—that exhibited a prospective-type delay activity before the

FIGURE 27.2 Image retrieval task for monkeys. The pair-association with color switch (PACS) task uses twelve pairs of colored pictures. When one member of each pair is shown, trained monkeys can retrieve and choose the other member of

the paired associates. The first pair consists of the picture G1 (green) and picture B1 (blue), the second pair consists of G2 and B2, and so on.

choice appeared. The delay activity was coupled with the paired associate that is not actually seen but is to be retrieved. This finding led us to a hypothesis that the pair-recall neurons were key elements of the image generation process in the task. Then we tested this hypothesis by developing a novel task, the pair-association with color switch (PACS) task. In this task the necessity for image generation and its initiation time were controlled by a color switch in the middle of the delay period (Naya, Sakai, and Miyashita, 1996). The PACS task consisted of PACS trials and control trials. The control trial, in which there is no color switch, corresponds to a trial of the conventional delayed matching-to-sample (DMS) task where the monkey chooses the same picture as a cue.

The sequence of events in a PACS trial or a DMS trial was as follows (see figure 27.3 and color plate 12). When the monkey pressed a lever in front of the video monitor, a gray square for fixation was presented at the center of the screen for 1 s (warning). Following the cue presentation of one of 24 pictures for 0.5 s, a square was presented during the delay period. The square's color was the same as the cue's color during the first part of the delay period (delay 1) for 2 s in PACS trials or for 5 s in DMS trials. In PACS trials, the square's color changed into the color of the paired associate after delay 1, signaling the initiation of retrieval, and then the second part of the delay period (delay 2) started. Delay 2 was not in-

cluded in DMS trials. To balance the visual stimulus conditions in the two trials, a gray square was presented for 1 s during the third part of the delay period (delay 3). After delay 3, a choice of two stimuli was shown randomly in two of four possible positions (arranged in two rows of two columns). The choice stimuli were the paired associate of the cue (correct) and a distracter (error) in PACS trials, while the choice stimuli were the same picture as the cue (correct) and a distracter (error) in DMS trials. The animal obtained a reward for touching the correct picture within 1.2 s. PACS trials and DMS trials were randomized. Extracellular discharges of single neurons were recorded with a glass-insulated tungsten microelectrode (Miyashita et al., 1989).

Figure 27.4 demonstrates the activity of a single inferotemporal neuron. The neuron exhibited typical differential responses between the PACS trial and DMS trial in delays 2 and 3, but not in delay 1, indicating that the neuronal firing was switched at the onset of delay 2 in the PACS trial. In this neuron one picture, green 7 (G7), elicited the strongest response during the cue period in both the PACS trial and the DMS trial. (We call this picture the “best picture” throughout the description of this neuron, irrespective of its delay response, although the “best picture” does not necessarily elicit the strongest delay response.) The excitatory response was maintained in delay 1 in both PACS and DMS trials. The paired associate of the best picture, blue 7 (B7), elicited no re-

FIGURE 27.3 Sequence of events in the image retrieval task. Both PACS trials and DMS trials use the same color stimuli shown in figure 27.2. In each trial of the task, a cue stimulus is presented, and the monkey is rewarded when he chooses the correct choice stimulus. The correct choice stimulus is the paired associate of the cue in PACS trials and the cue itself in DMS trials. PACS trials and DMS trials were given randomly.

Event sequence is the following: Warning, gray square for fixation (1 s in both trials); cue, one of 24 colored pictures (0.5 s); delay 1, fixation square the same color as the cue picture (2 s in PACS trials, 5 s in the DMS trials); delay 2, fixation square the same color as the paired associate of the cue picture (3 s in PACS trials); delay 3, fixation gray square (1 s in both trials); choice, a choice of two stimuli (1.2 s in both trials).

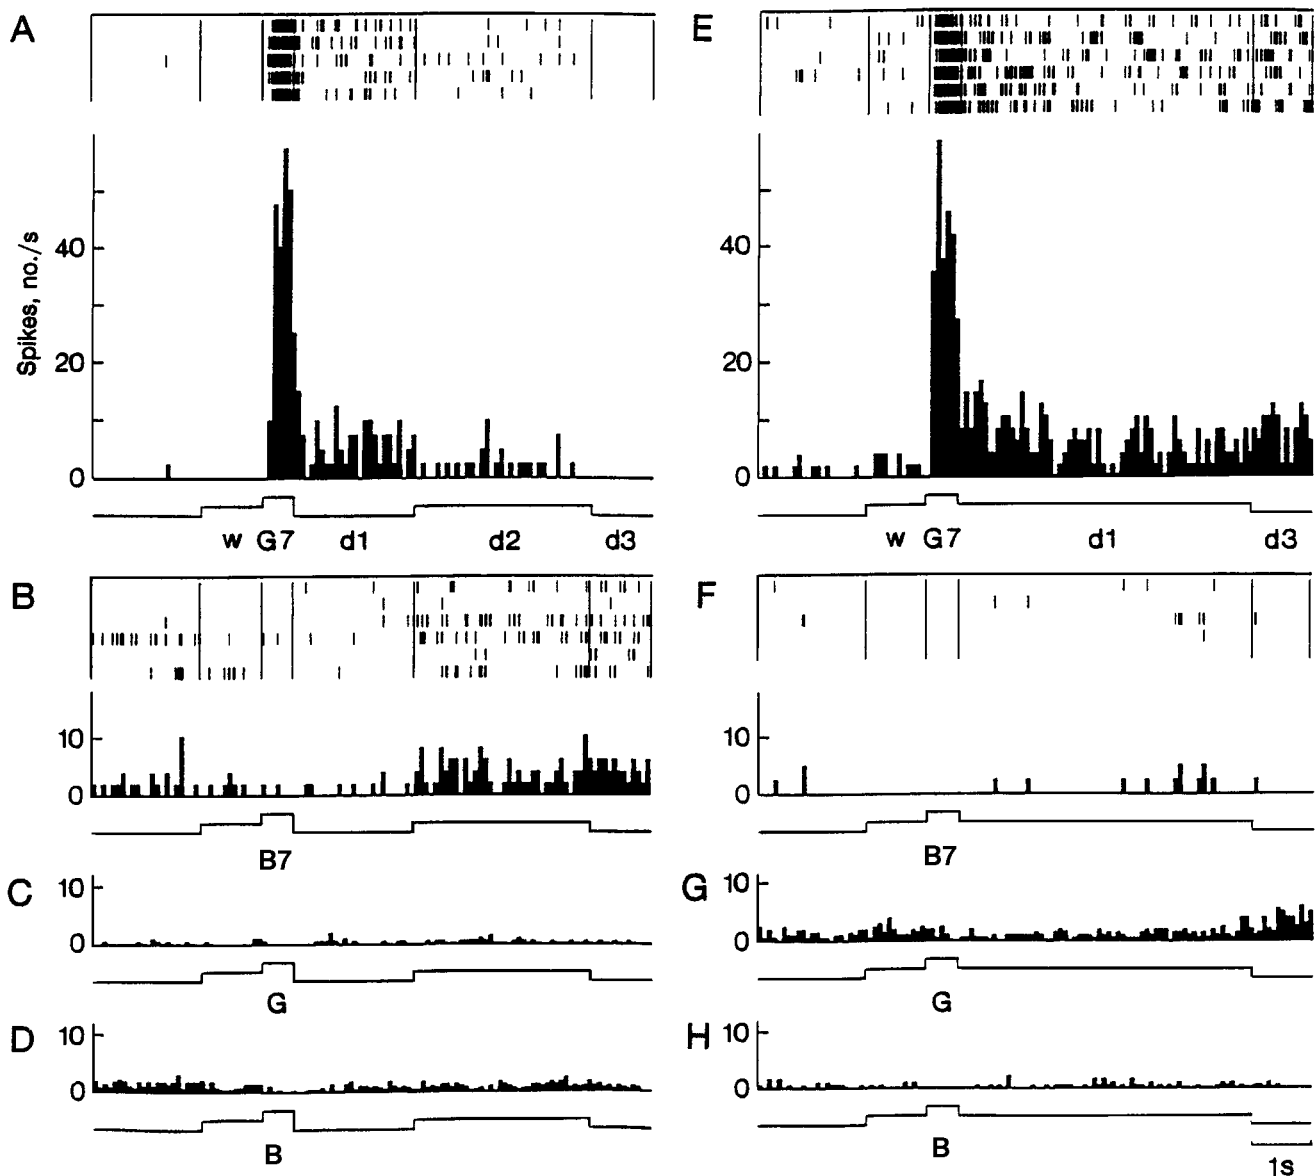

FIGURE 27.4 Neuronal correlate of image retrieval in the temporal cortex. Differential delay responses of a pair-recall neuron in PACS trials and DMS trials. Rastergrams of neural discharges in each trial and spike density histograms were obtained from a single inferotemporal neuron. Bin width, 80 ms. (A–D) Responses in PACS trials. (E–H) Responses in DMS trials. (A, E) Responses in trials for picture G7 as a cue. (B, F) Responses in trials for picture B7 as a cue. (C, G) Responses in trials for picture G1–G12 except G7 as cue pictures (G). (D, H) Responses in trial for picture B1–B12 except B7 as cue pictures (B). Picture G7 elicited the strongest cue response in both tasks

sponses during the cue period and whole delay period in the DMS trial. In contrast, when B7 was presented as a cue in PACS trial, this neuron started to respond just after the onset of delay 2 when the square's color changed from the cue's color (blue) to that of the paired associate (green).

(A, E). Note the suppressed response during delay 2 and delay 3 in PACS trials (A), but not in DMS trials (E). We called this phenomenon the pair-suppression effect. In trials for picture B7 as a cue, no response was observed during the cue period in both tasks (B, F). Note the enhanced response during delay 2 and delay 3 in PACS trials (B), but not in DMS trials (F). We called this phenomenon the pair-recall effect. In trials for picture G and B as cues, no responses were observed in both trials (C, D, G, H), indicating that there was no significant color effect (Naya, Sakai, and Miyashita, 1996).

Figure 27.5 quantifies these stimulus-specific activities of this neuron in PACS trials (see color plate 13). Only the stimulus G7 activated the cell during the cue period (top). In delay 1, this neuron continued to be active only for G7 (middle). However, in delays 2 and 3, when the retrieval of the paired associate was required,

STIMULUS SELECTIVITY OF AIT NEURON IN PACS

FIGURE 27.5 Stimulus selectivity of the inferotemporal neuron (same as that in figure 27.4) is shown in different task periods (top, cue period; middle, delay 1; bottom, delay 3). The ordinate shows the mean discharge rate in each task period after the presentation of a cue stimulus; cue stimuli are labeled as “pair No.” on the abscissa (G1 = green histogram bar in No.1; B1 = blue histogram bar in No.1; etc.). This neuron selectively responded to the cue stimulus G7 during the cue period. Note that the cue stimulus B7 does not elicit any response during the cue period and delay 1 in this neuron, but during delays 2 and 3 the same neuron became suddenly active.

the responses were switched from G7 to B7 (bottom). In other words, in the trial when B7 was presented as a cue, the cell was not active until delay 1, but the cell became suddenly active during delays 2 and 3, where the retrieval of G7 was required. Summing up, the cell became active when the image of its best picture (G7) should be recalled from memory. The picture-selective activation after the color switch in PACS trials is called the pair-recall effect.

It is important that the pair-recall effect cannot be due to the effect of the square's color, since other stimuli, either green or blue, did not induce a similar effect (figure 27.5, bottom). This was confirmed by the facts that the pair-recall effect continued from delay 2 into delay 3, in which the square's color was the same gray in both PACS and DMS trials, and that the pair-recall effect was found in PACS trials but not in DMS trials (figure 27.4).

FIGURE 27.6 Pair-recall effect in the PACS task. Discharge rates in trials where the best picture's paired associates were used as a cue in PACS and DMS trials. Each circle denotes the average firing rate for one of single inferotemporal neurons recorded ($n = 15$). In the PACS trials, activities during delay 3 (d3) were higher than those during delay 1 (d1) for most of the 15 cells. In the DMS trials, activities during d3 were not significantly different from those during d1 (Naya, Sakai, and Miyashita, 1996).

Figure 27.6 compares the responses of 15 cells that showed delay responses and were held long enough to complete PACS and DMS trials with all the stimuli. The number of spikes was counted by collecting the trials whose cue picture was the best picture's associate. The effect of the trial classes (PACS vs. DMS) on the delay response was significant [$F(1,14) = 19.8, p < .001$], and there was an interaction between the trial classes and period [$F(1,28) = 12.2, p < .005$]. We further analyzed responses among periods in each trial class (PACS or DMS), and responses between the trial classes in each period. In both PACS and DMS, responses in delay 1 remained equal to warning responses. These delay 1 responses were thus independent of the trial classes. In delay 3 of PACS, the responses were significantly stronger than those in delay 1 ($t = 3.5, p < .005$), while the delay 3 responses in DMS trials remained equal to the delay 1 responses. The delay 3 responses in PACS trials were significantly stronger than those in DMS trials ($t = 5.2, p < .001$). These results confirmed that the pair-recall effect is triggered by the color switch.

All of the above results strongly support the hypothesis that these neural discharges represent the active internal representation of a specific object in mind (the “image” of G7 in the case of figures 27.4 and 27.5). But how does this neural firing arise? What kind of machinery could drive the pair-recall neuron in delay 2/3 in spite of null activity in delay 1? It might depend on a

top-down input from the prefrontal cortex. Indeed, we recently found that, under an experimental design with a pair-association paradigm, prefrontal cortex could instruct the inferotemporal cortex to retrieve a correct memory of an object, even without bottom-up sensory input to the inferotemporal cortex (Hasegawa et al., 1998). However, it was also confirmed that only the posterior association cortex could hold the specific information on the paired associates in long-term memory (Hasegawa et al., 1998). Thus the neural mechanism for the image generation should involve specific communication between the pair-recall neurons and the neurons that encode the paired associates in long-term memory.

Let us now consider the neuronal mechanisms that encode the long-term memory of objects.

Inferotemporal neurons that encode the long-term memory of the paired associates

In previous studies (but with monochromatic paired associates), we found neurons that selectively encoded the associative relation between the paired associates (Sakai and Miyashita, 1991). To find out the neuronal correlates of the long-term memory of the paired associates, we trained monkeys to memorize the paired pictures (a monochromatic version of figure 27.2). We recorded single neuron activity and tested whether cells tended to respond preferentially to both of the paired associates, in spite of the fact that both stimuli had no geometric similarity. In the anterior ventral part of area TE (TEav), we found some patchy areas in which many neurons preferentially responded to both of the paired associates (the “pair-coding neuron”). We analyzed sampled cells by calculating response correlation using pair index or correlation coefficients (Sakai and Miyashita, 1991; Higuchi and Miyashita, 1996). The frequency distribution of these indices revealed that the paired associates elicited significantly correlated responses in these areas. This result provides strong evidence that inferotemporal neurons acquire stimulus selectivity through associative learning and that the selectivity reflects a stimulus–stimulus association among geometrically different complex forms.

Role of the interaction between the medial temporal lobe and inferotemporal cortex

Now we can examine the encoding mechanisms—specifically, the role of the interaction between the medial temporal lobe and inferotemporal cortex in the formation of declarative long-term memory (Squire and Zola-Morgan, 1991; Squire, 1987). Using behaving monkey preparation with the pair-association task, we investigated the hypothesis that limbic neurons undergo rapid modifica-

tion of synaptic connectivity and provide backward signals that guide reorganization of forward neural circuits to (and/or in) the inferotemporal cortex. This hypothesis has anatomical support in that inferotemporal cortex receives massive backward projections from the medial temporal lobe, especially from the perirhinal cortex (Van Hoesen, 1982; Webster et al., 1991; Suzuki and Amaral, 1994a,b). Thus the hypothesis for the role of the backward signal in the consolidation process specifically predicts that a lesion that includes the perirhinal cortex would impair the formation of the associative code for pictures in the inferotemporal neurons (figure 27.7). We now test this prediction.

We combined single-unit recording in the chronic monkey preparation with surgical manipulation so that individual inferotemporal neurons become devoid of the backward signals but can receive forward signals when visual stimuli are presented. We prepared a specific experimental design to run this project (figure 27.7). Backward neuronal connections from the limbic system to the inferotemporal cortex were interrupted by a lesion of the perirhinal cortices. But because a bilateral lesion would impair the monkeys’ behavior in the pair-association task (Murray, Gaffan, and Mishkin, 1993), the perirhinal/entorhinal cortices were lesioned unilaterally. With the unilateral lesion, the inferotemporal cortex of the lesioned side could receive information from the contralateral inferotemporal cortex. Receptive fields of inferotemporal neurons cover both hemifields before the lesion. In order to remove the interhemispheric signal from the healthy contralateral inferotemporal cortex, we surgically cut the anterior commissure (AC) at the beginning of the experiment. This surgery disconnected the anterior temporal cortex of each hemisphere from the other, since most commissural fibers of this area traverse the AC rather than the corpus callosum (Pandya, Karol, and Lele, 1973; Demeter et al., 1990). With this surgically manipulated chronic monkey preparation, we tested the ability of inferotemporal neurons to represent associations between picture pairs.

Two adult monkeys (*Macaca fuscata*) were trained in the pair-association task. The AC was transected before the learning of the task (figure 27.8B). After recovery, the monkey was trained with a set (set A) of the paired associates to the criterion performance level; then extracellular spike discharges of single neurons in the anterior inferotemporal cortex were recorded as a prelesion control, as reported in previous studies (Miyashita, 1988; Miyashita and Chang, 1988; Sakai and Miyashita, 1991). Then we deprived inferotemporal neurons of backward neural information by unilateral ibotenic acid lesions of the entorhinal and perirhinal cortices. The lesion covered both the medial and lateral banks of the rhinal sulcus completely, and most of

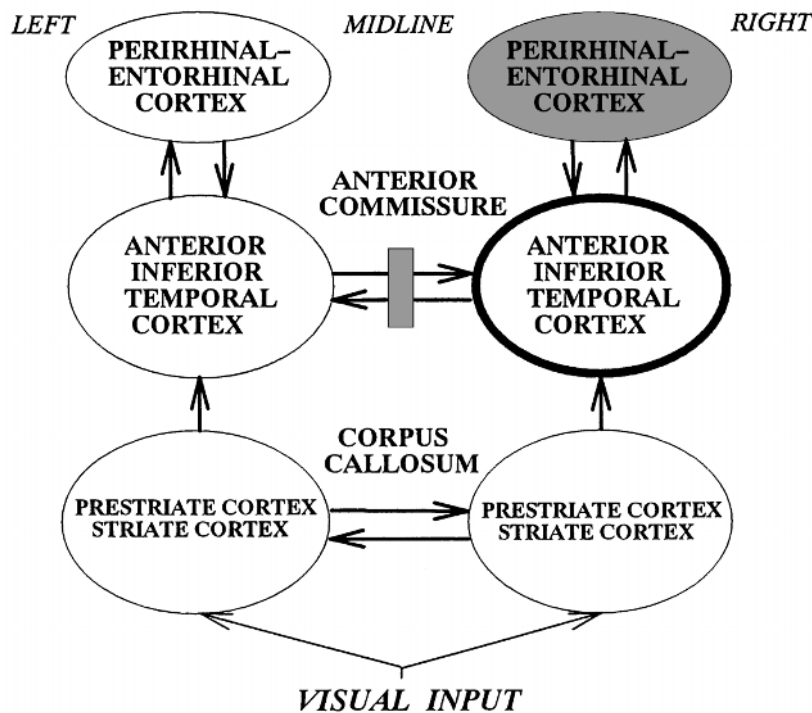

FIGURE 27.7 What is the role of the backward signal in memory formation? The inferotemporal cortex receives a backward signal from the limbic system as well as a forward visual signal

from the prestriate cortices. This diagram shows an experimental design to answer the question.

the entorhinal and perirhinal cortex (figure 27.8C–E). The lesioned cortex suffered atrophy, but fibers in the underlying white matter were left unharmed. After the ibotenic acid injection, the monkeys were trained with a new set of paired associates (set B). Then extracellular spike discharges of single neurons were recorded from the same area as that in the prelesion control. Correlation coefficient was used to analyze pair-coding responses of these cells (Higuchi and Miyashita, 1996). The response variability of the cells was evaluated before and after the lesion by a response variability index. The index was defined in each cell as the ratio of the standard deviation of firing rates among the trials for the optimum stimulus over the mean firing rate for the optimum stimulus. Larger values of this index indicate more trial-to-trial fluctuations of the responses.

Figure 27.9 compares the responsiveness of the cells before and after the lesion. The results of two monkeys were not significantly different ($p > .25$) in a two-way ANOVA in any of the indices and have been pooled. Prior to the ibotenic acid lesion, we examined the responses of 92 cells. The distribution of the correlation coefficient showed that the paired associates elicited significantly correlated responses in the control ($p < .01$; Wilcoxon's signed-rank test), confirming the conclusion of our previous report (Sakai and Miyashita, 1991). After the lesion, we examined the responses of 75 cells, and

the cells responded to the pictures (38 ± 2 spikes/s) even more strongly than the control (31 ± 1 spikes/s). However, the correlation coefficients were reduced ($p < .05$) and dropped to chance level after the lesion. The spontaneous discharge rates were not significantly different among the groups ($p > .2$). We also tested with a response variability index whether the cells exhibited any sign of pathological firing after the lesion. The index did not differ significantly between the groups ($p > .6$). We conclude that lesion of the entorhinal and perirhinal cortices disrupted the associative code of the inferotemporal neurons between the paired associates, without impairing the visual response to each stimulus. The results support the view that inferotemporal neurons have the ability to represent the long-term mnemonic code between picture pairs and that this ability is critically dependent on backward connections from the perirhinal cortices to the inferotemporal neurons.

Circuit reorganization in the primate temporal cortex

Then we ask why the limbic–neocortical interactions are so important. By our hypothesis, perirhinal neurons undergo rapid modification of synaptic connectivity and provide backward signals that guide reorganization of forward neural circuits to (and/or in) the inferotemporal

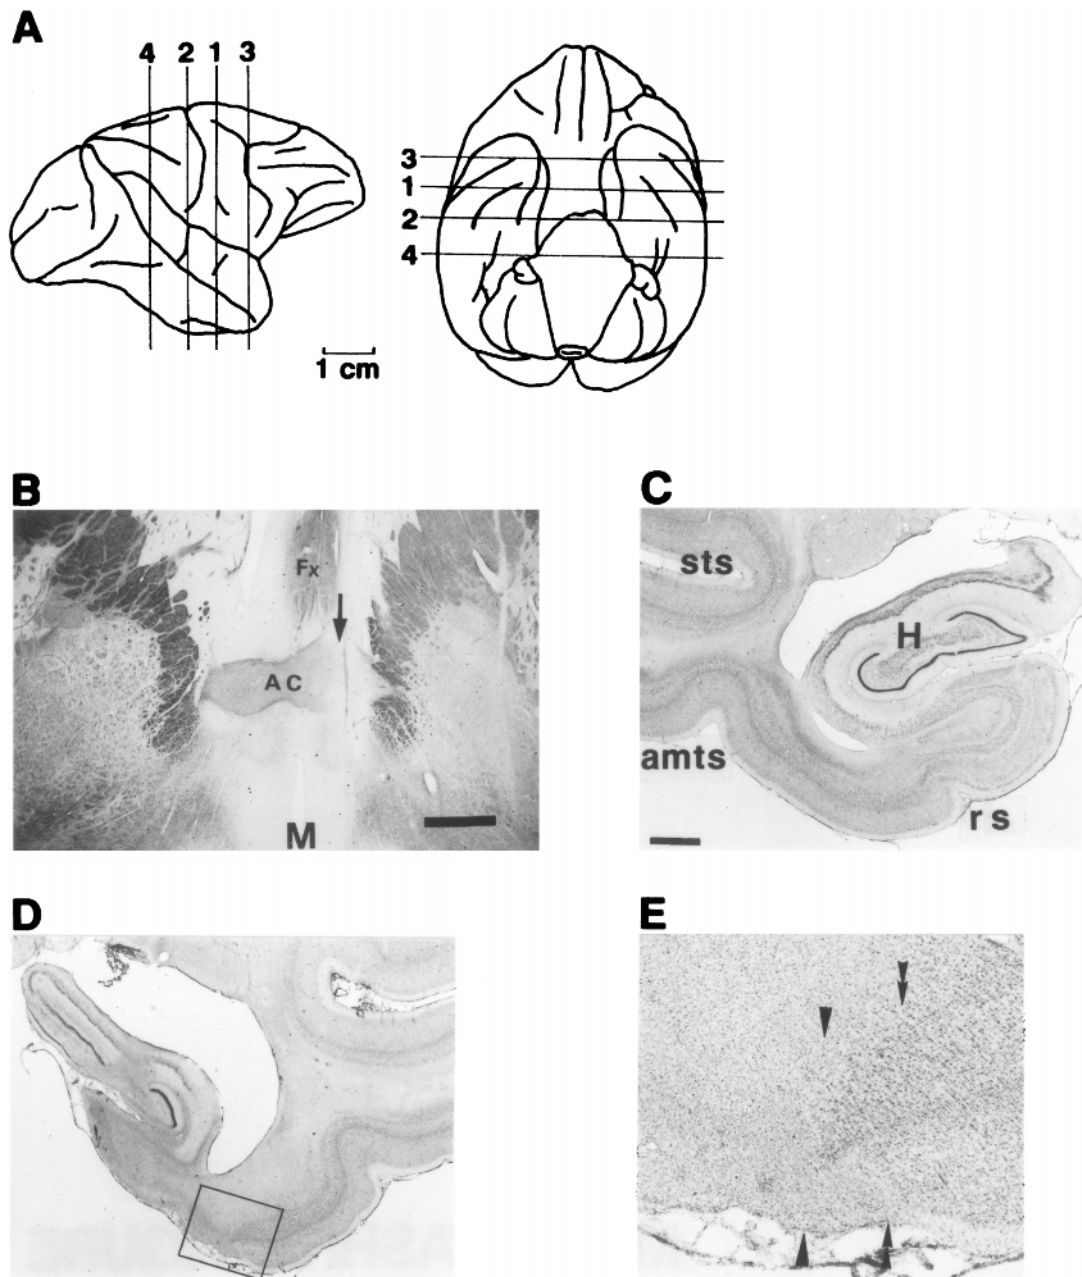

FIGURE 27.8 Unilateral ibotenic acid lesion of the entorhinal and perirhinal cortices. (A) Lateral (left) and ventral (right) view of a monkey brain, indicating the locations of sections used in the following panels (section 1 for panel B, 2 for C–E). Scale bar, 1 cm. (B) Fiber-stained coronal section through the anterior commissure (AC). The AC was surgically cut (arrow) just to the right of the midline (M). The fornix (Fx) was left intact. Scale bar, 2 mm. (C) Cresyl violet-stained coronal section showing the left (intact) entorhinal and perirhinal cortices.

Scale bar, 2 mm. (D) Same section as C, but showing the right entorhinal and perirhinal cortices that were lesioned by ibotenic acid. (E) Higher magnification of the area outlined in D. Double arrowheads indicate the border between intact area (to the right) and incompletely lesioned area. Arrowheads indicate the border between completely (to the left) and incompletely lesioned area. cortex. To explore the first part of this hypothesis, we employed a molecular biological approach. If the hypothesis is true, we should be able to detect the expressions of molecular markers for synaptic plasticity in the

monkey temporal cortex (especially perirhinal cortex) during learning of the pair-association task. As the first step, we attempted to test the expression of immediate early genes (IEGs).

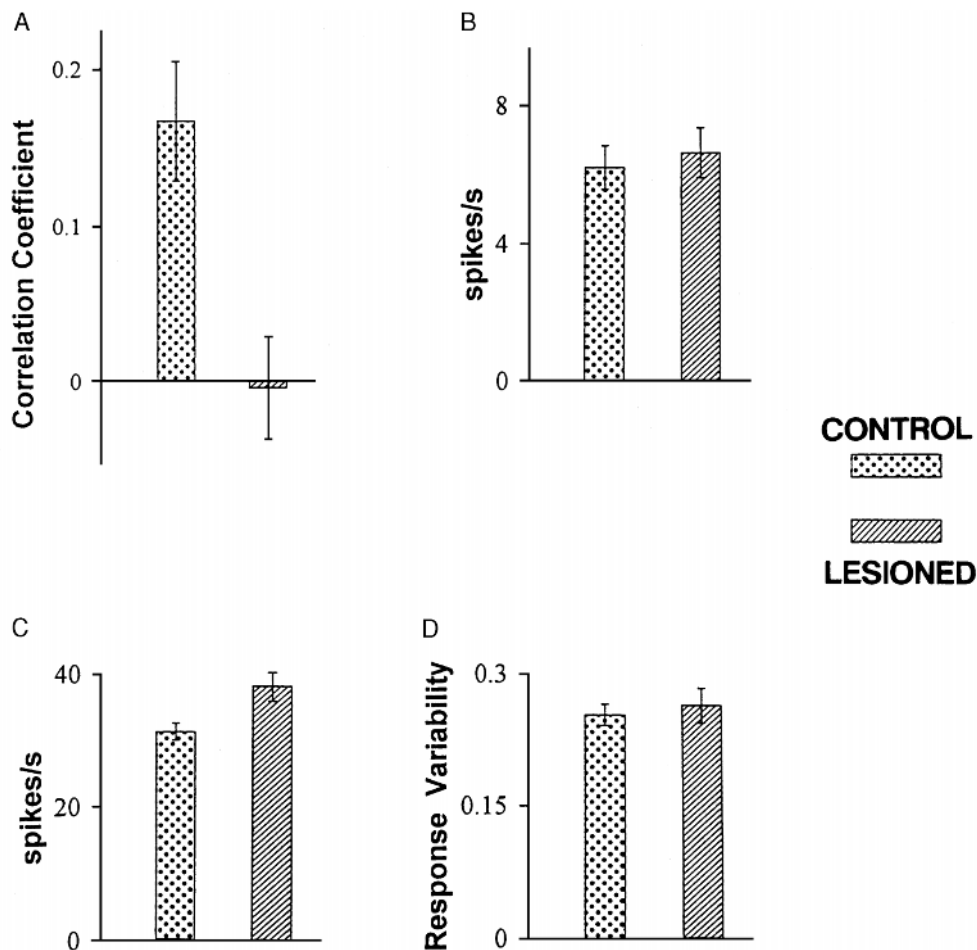

FIGURE 27.9 Effects of the lesion of the entorhinal and perirhinal cortices upon neuronal responsiveness in the pair-association task: (A) Correlation coefficient; (B) spontaneous discharge rate; (C) maximum discharge rate with spontaneous discharge subtracted; (D) response variability. These indices

were compared among two groups: (1) neurons that were recorded prior to the lesion using the set-A stimuli (stippled bar, $n = 92$); (2) those recorded after the lesion using the set-B stimuli (hatched with thin line, $n = 75$). Data are shown as mean \pm s.e.m.

IEGs are a class of genes that show rapid and transient, but protein synthesis-independent increases in transcription. Many IEGs encode transcription factors such as Fos, Jun and ZIF268; and these IEGs, especially *zif268* (the gene that encodes for ZIF268), have been hypothesized to play crucial roles in transduction of neuronal electric signals into more permanent synaptic organization (Morgan and Curran, 1991; Bailey and Kandel, 1993). For example, the induction of *zif268* in the dentate gyrus is closely correlated with the induction of long-term potentiation (LTP) (Abraham et al., 1993; Worley et al., 1993). We attempted to determine in which temporal cortical areas IEGs were expressed during visual long-term memory formation in the primate. We trained monkeys to learn two different cognitive memory tasks, a visual pair-association task and a visual discrimination task. The visual pair-association task required the monkeys to memorize visual stimulus-stimulus associations (Sakai and Miyashita, 1991; Murray,

Gaffan, and Mishkin, 1993). The other task, the visual discrimination task, required them to memorize stimulus-reward associations (Iwai and Mishkin, 1969). The types of learning required in these tasks are different since they are sensitive to lesions in different brain areas and the visual pair-association task was more sensitive to lesions of the medial temporal cortex (Iwai and Mishkin, 1969; Murray, Gaffan, and Mishkin, 1993).

To investigate formation of the stimulus-stimulus association memory but not the skill-based (or habit-like) memory (Mishkin, 1982) incidental to the learning paradigm, we designed a specific learning procedure (figure 27.10). We first trained the monkeys to learn a “rule” or “strategy” of the tasks, which is considered to be related to the skill-based memory, using a set of 24 pictures (the *training set*). After the monkeys’ performance reached a plateau level with the training set, a new stimulus set (the *test set*) was introduced. The monkeys’ performance was at a chance level in the first day with the test set. The

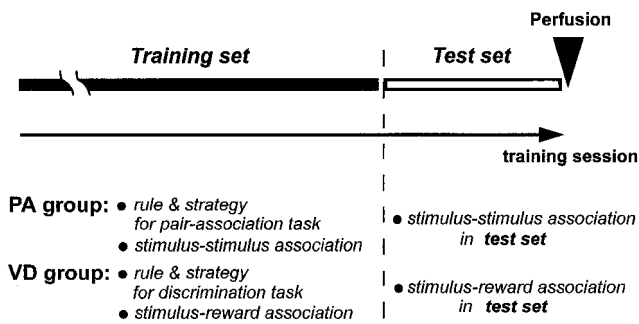

FIGURE 27.10 Experimental design to detect learning-induced activation of molecular markers in monkeys. To detect the expression of a gene that is specifically related to the paired-associate learning, two different control procedures were introduced. First, the monkeys learned the rule and task strategy during the learning of the *training-set* stimuli, and then the expression of molecular markers was detected during the learning of the *test-set* stimuli. Second, the expression during paired-associate learning was compared with that during visual discrimination learning. The paired-associate learning and visual discrimination learning used the same visual stimuli, the same motor responses, and the same amount of rewards.

performance improved in 5–6 subsequent days, but did not reach a plateau phase. Then the monkeys were perfused immediately after completion of 90 minutes' learning on the perfusion day. The brain blocks were frozen in dry-ice powder and sections (32 μ m) were cut using a cryostat and stained immunohistochemically. The specificity and reactivity of the anti-ZIF268 antibody has been described (Okuno, Saffen, and Miyashita, 1995). The anti-ZIF268 antibody specifically recognized an 86-kDa protein in the nuclear extracts from monkey cerebral cortex in immunoprecipitation experiments (Okuno and Miyashita, 1996).

We compared expression of ZIF268 in the anterior temporal cortex of the monkeys during visual paired-associate learning and visual discrimination learning. The presentation of visual stimuli, numbers of emitted motor responses, and amounts of given reward were equalized in the two tasks. In the case of visual paired-associate learning, the intensely ZIF268-immunopositive neurons were accumulated in patches in the ventral surface of the inferior temporal gyrus. The patches were centered in layer IV and spread into both superficial (II/III) and deep (V and VI) layers. The patchy pattern was found in several consecutive sections and was specific to ZIF268, since other IEG products (cFos and JunD) did not show such patterns in adjacent sections (Okuno and Miyashita, 1996).

The distribution of ZIF268 expression in the monkey temporal cortex was quantified by image analysis (Okuno and Miyashita, 1996) and displayed on a two-dimensional unfolded map (figure 27.11; see color plate

14). In each monkey with visual paired-associate learning, ZIF268 was expressed at high levels in a strip parallel to the rhinal sulcus in an anterior–posterior axis, particularly in several patches in this strip (PA1–PA3). ZIF268 was expressed at relatively low levels and was distributed more homogeneously in the monkeys with visual discrimination learning (VD1–VD3). The inferior temporal gyrus is composed of three cytoarchitectonically and connectionally distinct areas (area 35, area 36, and the ventral part of area TE) (Suzuki and Amaral, 1994a). The expression of ZIF268 in the monkeys during visual paired-associate learning was prominent in area 36. By contrast, in area 35, which is medially adjacent to area 36, ZIF268 expression levels were low during both types of visual learning. A two-way ANOVA on the mean expression level (two learning tasks and three brain areas) revealed a significant effect of task [$F(1,4) = 12.05$, $p = .025$] and of area [$F(2,8) = 17.73$, $p = .001$]. The expression in area 36 was significantly higher during visual paired-associate learning than during visual discrimination learning [1.34 ± 0.07 and 0.96 ± 0.04 (\pm s.e.m., arbitrary units), respectively; $p = .01$]. In area 35, the expression levels in the two monkey groups were similar and were not significantly different (pair-association, 0.65 ± 0.09 ; discrimination, 0.58 ± 0.05 ; $p > .5$). In ventral TE, the difference did not reach statistical significance ($p = .22$), but there might be a tendency for higher expression of ZIF268 in the monkeys with visual paired-associate learning (pair-association, 1.11 ± 0.15 ; discrimination, 0.85 ± 0.08). These results support the hypothesis that perirhinal neurons would undergo rapid modification of synaptic connectivity during learning of the visual pair-association task.

Conclusion

In this chapter, we examined neural mechanisms underlying memory retrieval and the consolidation process by single-unit recording and molecular biological methods. For this purpose we devised a visual pair-association memory task for monkeys. The task requires the monkey to encode associative relations between visual objects and to retrieve the high-level internal representation (the “image”) of the paired associate according to a cue stimulus. We proposed that the visual memory is organized as structured bundles of associations between objects in the inferotemporal cortex (Miyashita, 1993) and that the retrieved image is activated in the neural network of the inferotemporal cortex. The pair-association with color switch (PACS) task, in which the necessity for image retrieval and its initiation time were controlled by a color switch, provided particularly compelling evidence for the role of inferotemporal neurons

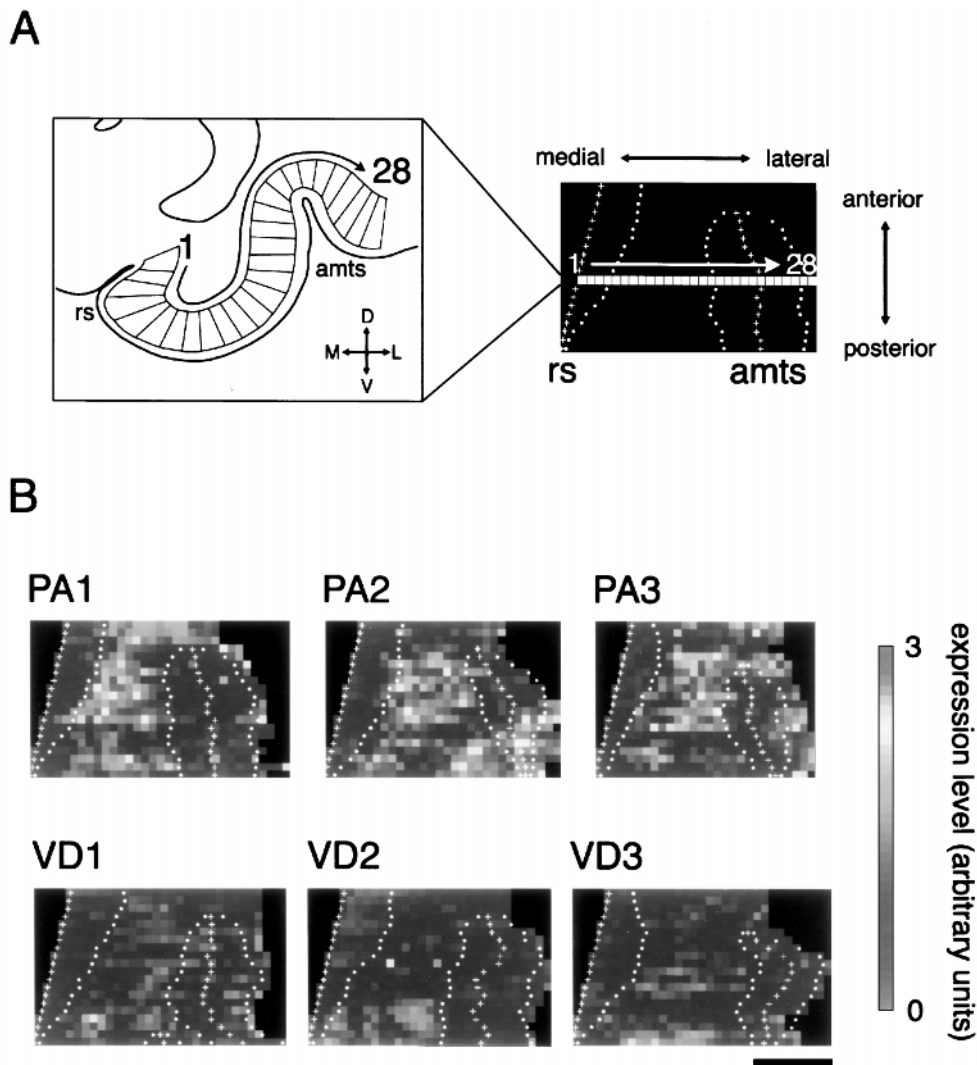

FIGURE 27.11 Two-dimensional unfolded maps of the monkey temporal cortex indicating ZIF268 expression levels. (A) Line drawing of 28 radial, segmented areas in a coronal section through the right medioventral temporal cortex (left). The cortical area in each section was subdivided into a number of radial segments. To display the spatial distribution of ZIF268 expression levels, the segmented areas were reconstructed as a two-dimensional unfolded map (right). The fundus and lip of a sulcus are outlined by white crosses and dots, respectively. Serial sections were aligned along the fundus of the rhinal sulcus. rs = rhinal sulcus; amts = anterior middle temporal sulcus; D, L, V, M = dorsal, lateral, ventral, medial. (B) The expression

levels of ZIF268 in the temporal cortex of individual monkeys. The density of reaction products of ZIF268-immunostaining in the segments is indicated on the unfolded maps (similar to the right panel in A) in pseudocolor representation. The maps from monkeys with visual paired-associate learning (PA1–PA3) and visual discrimination learning (VD1–VD3) are shown in upper and lower panels, respectively. The values are normalized so that the mean density of the reaction products of all segments from all six monkeys is 1.0 (Okuno and Miyashita, 1996). The boundaries of cortical areas were indicated by gray dots. Scale bar, 10 mm (Okuno and Miyashita, 1996).

(Naya, Sakai, and Miyashita, 1996). The activated high-level representation in inferotemporal cortex could be the origin of backward signals that appear to reach topographically organized visual areas when an imagery task requires reconstruction of the detailed local geometry of the image (as in counting the columns of the Pantheon), as demonstrated in neuroimaging and psychophysical studies (Ishai and Sagi, 1996; Miyashita, 1995; Kosslyn, 1994; Roland, 1993).

The backward signal from the medial temporal lobe to the inferotemporal cortex plays a distinct role in memory consolidation. We analyzed the interaction between the perirhinal cortex and area TEav during the formation of the visual paired-associate memory in monkeys. We hypothesized that the interaction is critical since perirhinal neurons might undergo rapid modification of synaptic connectivity and could provide a backward signal to guide reorganization of forward neural

circuits in (and/or to) area TEav. The results of single-unit recording combined with neurotoxic lesions, as well as detection of the expression of molecular markers for synaptic plasticity, supported the hypothesis. However, the study has completed only the first stage of investigation, and there are many missing links. For example, it is believed that the induced transcription factors regulate expression of late-response genes which probably contribute to the synaptic plasticity, especially to morphological changes (Bailey and Kandel, 1993). So far we have no data in monkey inferotemporal cortex supporting this line of speculation.

In the above studies, we extensively used the visual pair-association memory task for monkeys—an approach that offers many advantages. However, in this task (even in the PACS task), the image was generated in a simple way, in which a subject recalled a previously seen object. We humans use imagery in more flexible ways. First, we can combine or arrange objects in novel configurations in images. Second, we can also mentally draw patterns that we have never actually seen, and we can visualize novel patterns that are not based on rearranging familiar components. To make these image computations possible, an imagery system should contain another subsystem—one that uses associative memory and constructs local representations on the basis of a global image by top-down attentional shift (Farah, 1990; Kosslyn, 1994). Anatomical localization of the subsystem might be hypothesized in the dorsolateral prefrontal cortex, but evidence is still scanty (Fuster, 1989). It is noted that, although we believe depictive representation lies in the deepest structure for image generation (Kosslyn, 1994; Miyashita, 1995), propositional representation may also generate imagery by the use of this subsystem, especially in humans (Pylyshyn, 1981). Characterization and neurophysiological analysis of this subsystem would provide further constraints on the neural basis of imagery and its conscious activation.

28 Physiological Studies of Face Processing in Humans

GREGORY MCCARTHY

ABSTRACT Face processing comprises perceptual and cognitive processes required for the recognition of a complex stimulus as a face, the identification of the particular face in view, and the analysis of facial expression. These and other components of face processing can be dissociated by brain lesions, suggesting that face processing relies on a distributed neural system. Recent physiological studies in humans have begun to supplement the lesion data in identifying critical nodes in this distributed system. Neuroimaging studies using positron emission tomography and functional magnetic resonance imaging have demonstrated that discrete regions of the fusiform gyrus are consistently activated when subjects view faces. Electrophysiological recordings from electrodes placed directly on the fusiform gyrus have further demonstrated that face-specific evoked activity occurs within 200 ms of face presentation. Electrical stimulation of these same sites has frequently led to transient prosopagnosia, strongly implicating these discrete brain regions in face processing. However, the specificity of these regions for face processing is still a contentious issue, as is the degree to which these fusiform face regions are modulated by top-down processing.

In addition to ventral occipitotemporal cortex, other brain regions are engaged by face processing. In general, tasks emphasizing face memory activate more anterior regions of the medial temporal lobe, including the parahippocampal gyrus and hippocampus. Faces also evoke activity in and near the superior temporal sulcus. This latter activation may reflect the processing of dynamic information related to the analysis of eye and mouth movements. Finally, the amygdala has been strongly implicated in the analysis of facial expressions, particularly fearful expressions, while the insula has been activated by expressions of disgust. These results suggest that the analysis of specific emotional expressions may be linked to neural systems involved in behaviors relevant to those emotions.

Face processing encompasses a large number of perceptual and cognitive processes including the extraction of the face from among other structures in the visual scene, the identification of the particular face in view, the access of the bearer's name and associated semantic information, and the analysis of facial expression to

determine the bearer's intentions and emotional state. The fast and accurate processing of faces confers a survival advantage—kin are easily identified and danger and threat are rapidly conveyed. The apparently effortless ability to identify faces has given rise to the notion that face processing is effected by special neural mechanisms, an idea lent credence by studies of patients showing that brain lesions can sometimes lead to profound deficits in face processing. However, face agnosia, or prosopagnosia, is often associated with other difficulties in object recognition, leading some investigators to conclude that the deficit is not face-specific (Bauer and Trobe, 1984; Damasio, Damasio, and Van Hoesen, 1982) but reflects a more general problem of within-category visual discrimination. This point has been contested in studies reporting patients with visual processing deficits that appear quite specific for faces (De Renzi et al., 1991; Farah et al., 1995). Other studies have demonstrated that aspects of face processing such as gender discrimination, face identity and analysis of facial expression can be dissociated by brain lesions (e.g., Adolphs et al., 1994; Sergent and Villemure, 1989) suggesting that face processing relies upon a distributed neural system.

Functional neuroimaging and neurophysiological studies have begun to supplement studies based upon the analysis of brain lesions in describing the functional neuroanatomy of face processing. Here we review neuroimaging and neurophysiological studies that have investigated the functional properties and specificity of different cortical regions for face processing. We limit our scope to studies of healthy adult humans, although pertinent references to the voluminous literature on prosopagnosia are provided where relevant. We do not attempt to review the many relevant studies concerned with the development of face processing in humans, deficits in face processing associated with psychiatric disorders, or physiological studies in nonhuman primates. The reader is directed to several excellent treatments of this topic (Bruce and Young, 1986; Farah, 1990; Milders and Perrett, 1993).

GREGORY MCCARTHY Brain Imaging and Analysis Center, Duke University Medical Center, and Veterans Affairs Medical Center, Durham, N.C.

We first consider studies that have addressed the neuroanatomical basis for visual object recognition and the distinction between faces and nonface objects. Several neuroimaging studies have tested the distinction drawn between visual processing of objects in the ventral portion of the brain, the “what is it” pathway, and of spatial locations in more dorsal brain regions, the “where is it” pathway (Ungerleider and Mishkin, 1982). Haxby and colleagues (Haxby et al., 1991) performed the first neuroimaging studies in humans that explicitly addressed this dichotomy using oxygen-labeled water (H_2^{15}O) and positron emission tomography (PET) to measure task-related changes in regional cerebral blood flow (rCBF). A face-matching task was used to stimulate the ventral object pathway, and dot-location matching was used to stimulate the dorsal spatial location pathway. A third task controlled for visual stimulation and motor responses. As predicted, the face-matching task activated the ventral occipitotemporal cortex while the dot-location task activated the superior parietal lobe. The dorsal-ventral distinction between location and face matching was confirmed in subsequent publications, even when all stimuli contained faces and only task instructions differentiated the object and spatial tasks (Haxby et al., 1993, 1994). As before, the face-matching task activated the ventral occipitotemporal region bilaterally, but the greater magnitude and spatial extent of activation occurred in the right hemisphere, particularly in the fusiform gyrus. This right hemisphere dominance for faces contrasts with a similar study (Köhler et al., 1995) that used objects other than faces. As in Haxby’s studies (Haxby et al., 1991, 1993), bilateral occipitotemporal activation was found for objects, but activation was greater and extended more anteriorly in the left fusiform.

Haxby (Haxby et al., 1991, 1993, 1994) and Köhler (Köhler et al., 1995) established that faces and nonface objects activate extensive regions of ventral occipitotemporal cortex bilaterally, with a right hemisphere bias for faces and a left bias for nonface objects. Malach and colleagues (1995) performed a study using functional magnetic resonance imaging (fMRI) to investigate early stages of visual processing that discriminate objects from nonobjects. Objects, including faces, activated a region (termed LO) that was localized to the lateral aspect of the posterior fusiform gyrus bilaterally. While activated by all objects, LO showed little activation for textures or “phase-scrambled” objects (created by scrambling the phase of the 2D Fourier transform of the objects and then performing an inverse transform,

thereby preserving the spatial frequency of the original objects). Malach reported that LO was equally activated by familiar objects and unfamiliar abstract shapes and suggested, therefore, that LO may represent a preliminary stage in object recognition prior to semantic analysis.

Sergent, Ohta, and MacDonald (1992) performed the first neuroimaging studies that attempted systematically to isolate components of face processing from the visual processing of nonface objects and lower visual stimuli such as sinusoidal gratings. A comparison of two discrimination tasks—face gender and sinusoidal grating orientation—yielded extensive posterior right occipital hemisphere activation (including the inferior, middle, and lateral occipital gyri and the right lingual gyrus) and less extensive left hemisphere activation (including the left middle occipital gyrus). A comparison of object discrimination and sinusoidal grating discrimination yielded extensive activation in the left occipitotemporal region, principally the fusiform gyrus, inferior and middle temporal gyri, the middle occipital gyrus, and superior parietal lobe. The areas activated by face gender discrimination that were not also activated during object discrimination included the ventral and inferior lateral occipitotemporal cortex of the right hemisphere, including the fusiform and parahippocampal gyrus, and the anterior medial temporal lobe bilaterally.

Our group (Puce et al., 1995) used fMRI to investigate responses to unfamiliar faces compared to equiluminant control stimuli consisting of the equiluminant piecewise scrambled faces. Faces activated the ventral occipitotemporal cortex bilaterally, primarily within the fusiform gyrus, with lesser activation of the adjacent occipitotemporal sulcus and inferior temporal gyrus. The volume of face-related activation in the right fusiform gyrus and adjacent occipitotemporal sulcus was approximately 160% of that obtained in similar regions of the left hemisphere. Similar activations were reported by Clark (Clark et al., 1996) who performed a fMRI study, using the same face-matching task as that in Haxby’s study (Haxby et al., 1993) and found the most reliable activation in the right fusiform gyrus. Also, Kanwisher (Kanwisher et al., 1996) compared faces to everyday objects and found that faces activated the right fusiform while objects activated the fusiform and parahippocampal gyri bilaterally.

The neuroimaging studies just reviewed consistently show that objects primarily activated ventral occipitotemporal cortex. Although the activation was usually bilateral, faces produced stronger activation of the right hemisphere while nonface objects produced stronger activation of the left hemisphere. Prosopagnosia is most frequently associ-

ated with bilateral lesions to the occipitotemporal cortex (Damasio, Damasio, and Van Hoesen, 1982), although right hemisphere damage has been shown to be sufficient to produce the deficit (De Renzi et al., 1994). The activation obtained in the PET studies was more spatially extensive than that obtained in the fMRI studies—a fact Clark (Clark et al., 1996) attributed to the spatial smoothing typically employed in PET studies. Across studies, the right fusiform gyrus was most consistently activated. Like Sergent (Sergent, Ohta, and MacDonald, 1992), Puce and colleagues (1995) also noted discrete activation in lateral cortex including the right middle occipital gyrus and lateral occipital sulcus and more anteriorly in the superior temporal sulcus. Lesser activation was noted in the left middle occipital gyrus.

Figure 28.1—an overlay of activation by faces obtained in a fMRI study by Puce and colleagues (1996)—illustrates several of the points raised above (see color plate 15). Bilateral activation of the fusiform gyri by faces (yellow-red overlay) is clearly evident, with some-

what more extensive activation obtained in the right fusiform. Activation by faces of right lateral cortex is also prominent.

While the neuroimaging studies are consistent in showing that faces activate ventral occipitotemporal cortex, they do not establish when such processing occurs. Our group has made electrophysiological recordings from implanted electrodes in extrastriate regions in patients being evaluated for seizure disorders. Allison and colleagues (1994a,c) reported a study of 24 patients who viewed faces, equiluminant piecewise scrambled faces, cars, scrambled cars, and butterflies. Faces, but not the other stimulus categories, evoked a surface-negative potential with a peak latency of approximately 200 ms (N200). Figure 28.2 presents an example of face-specific N200 recorded from a subdural electrode on the right lateral fusiform gyrus. Despite recording from widespread sites within the brain, N200 was evoked only from focal regions of the left and right fusiform, inferior temporal gyri, and from a lateral region centered

FIGURE 28.1 A comparison of activations evoked by faces (yellow-red overlay) and letterstrings (green overlay). Faces activated the fusiform gyrus bilaterally, and a region of lateral cortex in the right hemisphere. Letterstrings activated the oc-

cipitotemporal sulcus and intraparietal sulcus of the left hemisphere. The overlays shown represent the spatially normalized average of 12 subjects. (From Puce and associates, 1996.)

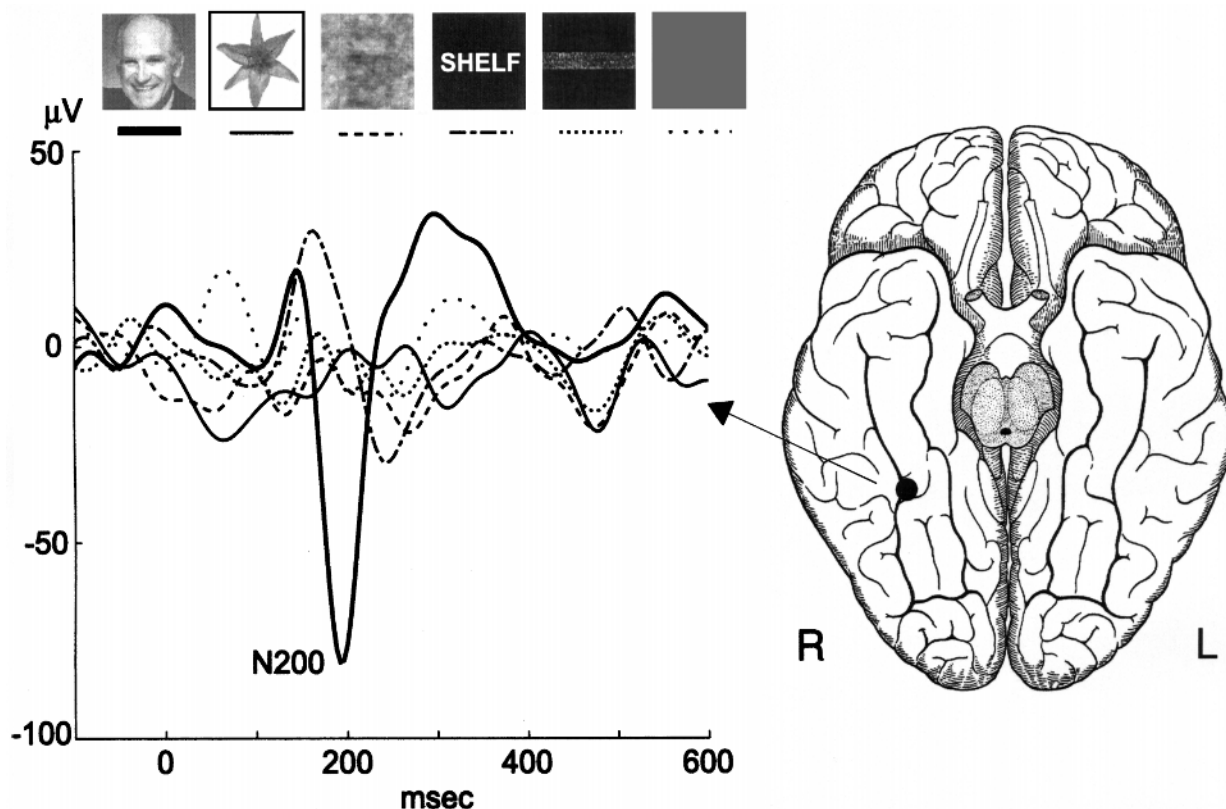

FIGURE 28.2 ERPs recorded from an electrode on the right lateral mid-fusiform gyrus in response to six different stimulus categories shown at the top: faces, flowers, phase-scrambled faces, nouns, phase-scrambled nouns, and gray rectangles. The subject was instructed to respond with a button press when-

ever a gray rectangle appeared. A large negative potential at approximately 200 ms (N200) was evoked only by faces. Electrodes immediately adjacent to this site (not shown) showed no face-specific ERPs.

upon the middle temporal gyrus (see below). Electrical stimulation of the face-specific N200 sites frequently produced a transient inability to name familiar faces but did not interfere with naming nonface objects (although extensive testing was not possible owing to clinical constraints). Adjacent to the more face-specific sites, color-sensitive ERPs were often recorded from the lateral lingual and medial fusiform gyrus. When these sites were electrically stimulated, color disturbances often resulted. No overlap was found between color and face-specific sites, although their close proximity may explain the frequent association of prosopagnosia and achromatopsia (e.g., Bruyer et al., 1983) in the human lesion literature. Allison's results (Allison et al., 1994a,c) suggest that discrete regions of inferior extrastriate visual cortex, varying in location between individuals, are specialized for the recognition of faces.

Figure 28.3 summarizes the locations of principal activations within the occipitotemporal region reported in ten representative studies using PET (open symbols), fMRI (closed symbols), and intracranial electrophysiology (asterisk).

Are faces special?

An enduring question in face perception is whether faces are unique objects processed by special neural machinery (Ellis, 1985). This question encompasses two related issues. The first asks whether deficits in face recognition following lesions are related to a general difficulty in discriminating items within a subordinate category (see Bauer and Trobe, 1984; Damasio, Damasio, and Van Hoesen, 1982). Faces may be special only in that they are usually processed to the subordinate level (the president's face) while other objects are processed to the base category level (a clock). Many prosopagnosic patients have difficulties with within-group discriminations such as cars or flowers (De Haan, Young, and Newcombe, 1991). However, some prosopagnosics appear to have a specific deficit for face recognition despite extensive testing with other object categories (Farah, Levinson, and Klein, 1995) and other patients have extensive object agnosias with intact face recognition (Moscovitch, Winocur, and Behrmann, 1997). Thus while many prosopagnosics have extensive difficulties in

FIGURE 28.3 A summary of principal occipitotemporal activations reported in ten representative studies concerned with face and object perception using different methodologies. Each symbol corresponds to the locations provided in each study in the coordinates of Talairach and Tournoux (1988). Four studies used PET methodology: (○) Face identity minus visual gratings (Sergent et al., 1994); (◇) face identity greater than spatial location (Haxby et al., 1994); (△) faces greater than control (Dolan et al., 1996); (□) degraded faces following exposure to undegraded faces (Dolan et al., 1997). Five studies used fMRI methodology: (+) Area LO (Malach et al., 1995); (●) face matching (Clarke et al., 1996); (■) faces greater than letterstrings (Puce et al., 1996); (▲) faces greater than objects (Kanwisher, McDermott, and Chun, 1997); (✱) faces among objects and nonobjects (McCarthy et al., 1997). One study used intracranial electrophysiological recording: (◆) Face-specific N200s (Allison et al., 1994a).

discriminating among other within-category items, this is not a necessary observation.

The electrophysiological data reviewed above generally support the thesis that specific neural regions are involved in at least the initial stages of face processing. Furthermore, other studies by our group found letterstring-specific sites within ventral occipitotemporal cortex that were clearly distinct from face-specific sites and from which face-specific and letterstring-specific N200 ERPs were evoked. (Allison et al., 1994a,c; Nobre, Allison, and McCarthy, 1994). Fol-

lowing upon these electrophysiological dissociations, Puce and colleagues (1996) contrasted faces, letterstrings, and textures in a fMRI experiment. Consistent with our prior study (Puce et al., 1995), bilateral (right hemisphere dominant) activation of the fusiform gyrus and the adjacent occipitotemporal and inferior occipital sulci was evoked by faces (figure 28.1, yellow-red overlay). In contrast, letterstrings evoked activation that was primarily restricted to the left lateral fusiform gyrus and occipitotemporal sulcus (figure 28.1, green overlay).

Puce and colleagues (1995) confirmed the strong dissociation between faces and letterstrings first observed electrophysiologically. However, it can be argued that letterstrings are themselves a special stimulus category and that the face-selective regions could have been activated by exemplars of other object categories. Kanwisher and colleagues (Kanwisher, McDermott, and Chun, 1997) addressed this and other issues in a series of neuroimaging studies. They first identified candidate face-specific areas by comparing faces to everyday objects. Regions for which faces evoked a stronger response than objects were identified in the fusiform gyrus in twelve of fifteen subjects. Ten of ten right-handed subjects had a right fusiform activation focus, and five of these ten also had a left fusiform focus. The average size of the right fusiform area was more than two times greater than the left fusiform area. Once identified, these fusiform regions were then used as regions of interest in subsequent studies using a subset of the same subjects.

Kanwisher first compared two-tone and scrambled versions of the same faces and found strong face activation despite equal luminance, thus confirming the results of Puce (Puce et al., 1995, 1996), who compared faces to equiluminant piecewise scrambled faces and textures. In a second experiment, Kanwisher compared unfamiliar faces to a set of unfamiliar houses. The faces evoked more than six times greater activation in the face areas than did houses, demonstrating the selectivity of the face areas for faces and further demonstrating that subordinate exemplars of any object category are not sufficient to activate the face region. The face areas responded more strongly to faces than to human hands, demonstrating that face area activation does not generalize to all body parts. Finally, subjects were tested with faces and hands in a task where the subject was required to respond to stimulus repetitions. Again, the face area was not activated by hands, even though the task required fine, within-category discrimination. Kanwisher (Kanwisher, McDermott, and Chun, 1997) concluded that the face area activation does not simply reflect subordinate-level categorization, but rather constitutes a neural module for face perception.

As reviewed above, Sergent, Ohta, and MacDonald (1992) reported that while faces and objects commonly activated the left fusiform gyrus, only faces activated the right fusiform, suggesting that faces may activate both face-specific regions in the right fusiform and more general object recognition regions in the left fusiform. Using similar reasoning, we hypothesized that faces presented in isolation may activate both general and specific recognition systems, and that activations evoked by faces in prior studies reflect both specific and general activation (McCarthy et al., 1997). To test this hypothesis, we presented subjects with a dynamic display in which control stimuli appeared briefly and asynchronously at different spatial locations for the duration of each run. In contrast, faces appeared among the control stimuli according to a periodic schedule. Approximately 1100 stimuli were presented in each 3-minute run—an average of 5 stimuli appeared on screen within each second. In one experimental condition, the control stimuli were examples of common objects. In the other condition, the control stimuli were phase-scrambled versions of the same objects with identical spatial frequency and luminance but otherwise unrecognizable. We predicted that faces among the scrambled nonobjects would evoke activation of the face-specific *and* general object recognition systems. However, faces presented among objects would only activate the face-specific system, as concurrent object processing would saturate the general object recognition system. Consistent with this hypothesis, we found bilateral activation within the fusiform gyrus evoked by faces presented among nonobjects, and more spatially restricted activation of a small region of the right fusiform gyrus for faces presented among objects.

To address the issue of within-category discrimination, additional studies were conducted in which the periodic presentation of faces was replaced by the periodic presentation of different flowers. We predicted that flowers presented among nonobjects would activate the general object recognition system. However, flowers presented among objects should evoke no fusiform activation, as the areas activated by flowers would now be activated continuously by concurrent object processing. The results were as predicted. Flowers evoked extensive fusiform gyrus activity bilaterally (but greater in the left hemisphere) when presented among nonobjects, but showed no activation when presented among objects. Results from a single subject are presented in figure 28.4 (see color plate 16).

Taken together, the results of Allison (Allison et al., 1994a,c), Puce (Puce et al., 1996), Kanwisher (Kanwisher, McDermott, and Chun, 1997), and McCarthy (McCarthy et al., 1997) present a strong case that relatively focal regions within the (primarily right) fusiform

gyrus respond specifically to faces and not to exemplars of other categories. However, it is also clear that faces evoke activity that is both specific and nonspecific within the fusiform gyrus; hence it is incumbent upon investigators to establish what portion of their obtained activations are face-specific before generalizing about the properties of this brain region.

While the studies reviewed above demonstrate that individual exemplars of different categories do not activate the face-specific fusiform region, this in itself does not invalidate the notion that within-category, or subordinate-level, processing poses an additional burden upon perceptual processes within the fusiform gyri. Gauthier and colleagues (1997) provide evidence that subordinate-level judgments about stimuli yield greater activation within the fusiform gyrus than base-level judgments about the same stimuli. Whether this result reflects a deeper depth of processing that further engages the fusiform object recognition system, or whether subordinate classification increases attentional demands or task difficulty, is not certain. The influence of attentional and mnemonic factors on processing in the fusiform face areas will be addressed in the next two sections.

A second issue regarding the special nature of face processing is whether the face areas defined in the prior studies represent cortex unique to face processing, or whether these regions have been tuned by long experience with homogeneous stimuli (Gauthier et al., 1997). To date, no neuroimaging study has directly addressed this issue, although behavioral evidence suggests that people can become experts in making fine discriminations among other categories of homogeneous stimuli (Gauthier and Tarr, 1997). Whether this expertise is instantiated in specific cortical regions has not yet been established.

Attention and faces

Neuroimaging studies have previously demonstrated attentional modulation in extrastriate regions specialized for color (Corbetta et al., 1990) and motion processing (O'Craven et al., 1997). Several authors have investigated the influence of attention upon neuroimaging activations evoked by face processing. At issue is the hypothesis that face perception is a fully automatic and obligatory process and, as such, does not require attention for its operation.

Sergent, Ohta, and MacDonald (1992) found that passively viewed faces produced no extrastriate activation relative to visual control stimuli whereas tasks requiring explicit processing of faces produced robust activation. However, subsequent fMRI studies have found discrete activation within the fusiform gyrus in passive viewing

FIGURE 28.4 Results from two adjacent slices in a single-subject study (McCarthy et al., 1997). Faces presented periodically within a dynamic montage of phase-scrambled objects (A) evoked activation within the right fusiform gyrus (D; yellow overlay). Faces presented within a montage of everyday objects (B) activated this same region (D, orange overlay). Bilateral activation (left hemisphere dominant) was observed in the fusiform gyri in both slices (G, H; yellow overlay) for flowers

conditions (Kanwisher et al., 1996; Kanwisher, McDermott, and Chun, 1997; McCarthy et al., 1997; Puce et al., 1995, 1996). Haxby and colleagues (1994) explicitly examined the role of attention by comparing a face-matching task and a spatial judgment task that used identical stimuli. The faces were spatially offset within larger enclosing boxes, and the relative arrangement of the boxes was the basis of the spatial task. Face matching evoked bilateral activation of the fusiform gyrus with the largest magnitude and greatest spatial extent in the right hemisphere. Additionally, face matching activated right prefrontal and orbital frontal cortex. Since both tasks

presented within a montage of phase-scrambled objects (E). However, no activation to flowers was obtained in any slice when presented within a montage of everyday objects (F). The activations in all figures were obtained using a split-*t* procedure; i.e., all colored voxels were significant in each of two replications of each task in which faces and flowers were presented at two different periods.

contained the same faces, this activation by the face-matching task above that obtained for the spatial task was presumed to reflect attention or other task-related processing.

One question raised by the preceding study is whether the rather extensive region activated by the face-matching task represented face-specific attentional modulation, or whether it represented a more general attentional modulation for other object features. Using fMRI, Clark and colleagues (1997) performed a study conceptually similar to Haxby's (Haxby et al., 1994) in which subjects were presented with color-washed faces,

with attention directed either to the faces or to the color. While many regions were commonly activated by both attention conditions relative to a sensorimotor control task, no areas were activated by attention to faces that were not also activated by attention to color. In contrast, a small region in the right lingual gyrus and collateral sulcus did appear to be selective for attention to color. Clark suggested that the lack of attentional modulation to faces may reflect automatic processing of faces in both attention conditions that did not benefit from additional attention.

In neither of the preceding studies was there independent localization of face-specific cortex prior to the attentional manipulations. Wojciulik (Wojciulik, Kanwisher, and Driver, 1998) first identified face-specific regions of the fusiform gyrus by engaging subjects in a passive viewing task contrasting faces with everyday objects (see Kanwisher, McDermott, and Chun, 1997). ROIs were then drawn for these regions and tested in each of two attention conditions. Each stimulus was composed of a central fixation cross with two faces and two houses arranged in vertical or horizontal pairs. On different trials, the subject was required to determine whether the faces or the houses were identical. The stimuli were briefly exposed to avoid saccades, and the spatial arrangement of stimuli provided no advantage for eccentric fixation. Attention to faces produced a relative increase in the signal intensity of the predefined face-specific ROI. Wojciulik and colleagues (Wojciulik, Kanwisher, and Driver, 1998) argued that while specialized visual machinery may exist for faces, their perceptual processing depends upon attention.

Despite some inconsistencies noted above, the weight of the neuroimaging data suggests that attention can influence the magnitude of activation within fusiform gyrus and challenges the notion that perception of faces is fully automatic. This conclusion is consistent with recent behavioral studies in which upright faces do not show the visual “pop-out” phenomena in displays containing inverted or distorted faces (Brown, Huey, and Findlay, 1997). These results are inconsistent, however, with electrophysiological data in humans that show little change in the N200 face-specific potential to repeated presentations of the same face (Puce, McCarthy, and Allison, 1997); data suggesting that an obligatory response to a face occurs within 200 ms of its appearance. Two issues are relevant. The first is that the neuroimaging studies demonstrating changes in activation by attention have not reported whether the attentional manipulations affected the subjects’ abilities to process faces. For example, while Wojciulik (Wojciulik, Kanwisher, and Driver, 1998) provides the best controlled study to date, it is not

certain that attending to houses prevented subjects from recognizing a familiar face, or from discriminating the gender of the faces.

The second issue concerns the timing of the attentional effect. It is possible that an initial phase of activation occurring within a face-specific area in the fusiform is automatic, and that task requirements engender further analysis that extends the duration of activation within the region under descending, or top-down, control. Recent intracranial electrical recordings from the fusiform gyrus in humans have shown that short-latency (~200 ms) ERPs specific to letterstrings are not influenced by attention, but that strong attentional effects occur at 600–800 ms at the same electrodes (Nobre, Allison, and McCarthy, 1998).

Memory for faces

FACE ENCODING AND RECOGNITION Several studies have distinguished neural systems involved in face encoding and recognition and systems involved with working memory for faces (Andreasen et al., 1996; Courtney et al., 1996; Courtney et al., 1997; Gur et al., 1997; Haxby et al., 1996; Haxby et al., 1995; Kapur et al., 1995). In the Sergent study reviewed above (Sergent, Ohta, and MacDonald, 1992), face gender discrimination primarily activated posterior occipitotemporal cortex. A further comparison of a famous face discrimination task with face gender discrimination yielded bilateral activation of more anterior regions, principally the fusiform gyri, the temporal poles, gyrus rectus, and the left middle temporal gyrus. The greatest activation occurred in the right, but not left, parahippocampal gyrus. Sergent concluded that the perceptual aspects of face processing primarily engaged right occipital regions while face identification engaged more anterior right ventral occipitotemporal regions, principally the mid-fusiform and parahippocampal gyri.

Sergent (1993) compared the results of her PET studies with the pattern of lesions in four prosopagnosic patients, all profoundly deficient in recognizing the identities of faces while reporting normal recognition of objects. Two of the patients sustained damage to the posterior aspect of the right fusiform gyrus, and were deficient in discriminating male and female faces. In contrast, one patient’s lesion invaded the white matter near the fusiform gyrus but not the gyrus itself. This patient was able to discriminate male and female faces and match different views of the same face. Thus, Sergent concluded that the extraction of physiognomic invariants (i.e., gender, emotion, and age) occurs posteriorly while the activation of pertinent memories associated with faces must occur anterior to the fusiform gyrus.

Consistent with this hypothesis were the findings from her fourth patient. This patient, who was unable to recognize the identity of faces but performed normally with regard to extraction of physiognomic information, had a postencephalitic lesion that destroyed the anterior right temporal lobe and left temporal pole.

Haxby reported a study contrasting the encoding of unfamiliar faces and the recognition of recently learned faces (Haxby et al., 1996). The face-encoding task primarily activated the right medial temporal region including the hippocampus and adjacent cortex. Additional areas of the left prefrontal cortex, left inferior temporal gyrus, and anterior cingulate cortex were also activated. In contrast, the face recognition task primarily activated the right prefrontal cortex, anterior cingulate cortex, bilateral inferior parietal cortex, bilateral ventral occipital cortex, and cerebellum. Thus, the right medial temporal regions appeared to participate in the encoding of new faces, but not in their subsequent recall. The hemispheric differences noted in the prefrontal region—left hemisphere for face encoding, right hemisphere for face retrieval—is consistent with the hemisphere encoding–retrieval asymmetry (HERA) model proposed by Tulving (Tulving et al., 1994).

Haxby used face matching as the control task; thus faces were included in all comparisons. It is notable, therefore, that no activation of the fusiform gyrus was observed in the face encoding and face recognition tasks above that evoked in the control task (although more posterior activation was noted). Haxby suggested that these areas perform the same perceptual processes independently of additional mnemonic activity (however, see Andreasen et al., 1996). Sergent (Sergent, Ohta, and MacDonald, 1992) and Haxby (Haxby et al., 1996) are consistent in their conclusions that memory for faces occurs at sites anterior to the fusiform regions identified as critical for initial perceptual face processing. They are also consistent in implicating right anterior medial temporal lobe structures in mnemonic processing of faces. However, Sergent implicates these structures in recognition of familiar faces whereas Haxby argues for their involvement in face encoding but not recognition.

The role of the hippocampus in face memory is unclear. Haxby (Haxby et al., 1996) implicates the right hippocampus in face encoding but not recognition. Andreasen (Andreasen et al., 1996) also found no hippocampal activation during face recognition. However, Kapur (Kapur et al., 1995) reported increased left hippocampal activation in both a famous-faces discrimination task and a recent-faces recognition task, when both were compared to a face-gender discrimination task.

This left-retrieval, right-encoding pattern of results reported for hippocampus is the opposite of that argued for prefrontal cortex (Tulving et al., 1994).

WORKING MEMORY FOR FACES Three recent neuroimaging studies from overlapping groups of investigators have been concerned with working memory for faces. Haxby and colleagues (1995) performed a PET study to distinguish areas involved with face perception from areas involved in transient storage of faces. They noted that activation of right inferior frontal cortex had been observed in their prior studies of face processing (Haxby et al., 1994), and hypothesized that this region might maintain the face representation when the face was not in view. Haxby and colleagues performed a delayed match-to-sample task in which the retention interval separating the sample and test faces was increased (1, 6, 11, 16, and 21 s) across runs. Thus the proportion of the interval devoted to viewing a face was diminished while the time required to keep the face in working memory increased. Consistent with their hypothesis, activation within an extensive region of the ventral occipitotemporal cortex showed a negative correlation with delay interval; i.e., the longer the interval, the less activation was obtained. This decreased activation was bilateral, but extended more anteriorly in the right hemisphere. The greatest effect was noted in the right posterior fusiform where activation by faces with retention interval delays beyond 11 s did not differ from sensorimotor control tasks. Haxby's group concluded that their results provided no evidence that striate and ventral extrastriate areas maintained an active, working memory representation of a face.

Haxby and colleagues noted that there was more activation in right anterior medial temporal regions including the hippocampus and parahippocampal gyrus for the face delay task with delays of 1 s than there was for simultaneous matching of faces. These areas were less activated at 6 s, and not at all at longer delay intervals. The interpretation of this finding is the same as that in the study reviewed above (Haxby et al., 1996)—that the right hippocampus is involved in encoding of faces, but not in their retrieval.

Courtney and colleagues used PET to contrast working memory for faces and for spatial locations (Courtney et al., 1996). Subjects were shown three consecutive faces at different spatial locations. A probe face was shown after a 1-s delay at one of the locations. In the location working memory condition, the subject indicated whether the location of the probe matched a location of one of the test stimuli. In the face working memory condition, the subject indicated whether the probe matched one of the test faces. Thus, the stimuli

were identical and only the instructions changed. Compared to the location working memory task, face working memory demonstrated significant activation of fusiform, parahippocampal, inferior frontal, and anterior cingulate cortices, as well as right thalamus and midline cerebellum. Since faces were the only objects used in this task, no conclusions can be drawn about the specificity of the working memory results for faces per se. However, since the stimuli were identical for both varieties of the working memory task, it is notable that working memory for faces evoked greater activation bilaterally in the occipitotemporal region. This suggests that some task component—working memory or attention—increased activation of the fusiform over that automatically evoked by faces. Both location and face working memory tasks activated a small region in the right posterior fusiform relative to a sensorimotor control task that did not use faces. Since face stimuli were present in both the location and face working memory tasks, this region may reflect automatic processing of face stimuli; i.e., the face module of Kanwisher, McDermott, and Chun (1997).

In a subsequent study, Courtney and colleagues (1997) performed a fMRI task using a delayed match-to-sample design. A multiple regression analysis was performed to identify the relative weighting at each voxel for three factors: nonselective transient visual responses, “face-selective” transient responses, and sustained activation over the 8-s retention interval. (As Courtney indicates, faces were the only object shown, so the regions designated as “face-selective” may in fact respond to other visual objects.) In general, the most posterior ventral occipital regions showed the highest weightings for nonspecific visual responses and the lowest (and nonsignificant) weightings for sustained activation. The opposite pattern was obtained in prefrontal regions where the anterior middle frontal gyrus showed the highest weighting for sustained activation and nonsignificant activation for nonspecific visual responses. This prefrontal region showed moderate selectivity for faces; however, previous studies have shown this region of the middle frontal gyrus to be active in both spatial and nonspatial working memory tasks (McCarthy et al., 1994, 1996). Face-selective responses were highest in the mid-to-anterior fusiform gyrus and inferior occipital sulcus, particularly in the right hemisphere. The fusiform maintained a small but significant level of activation during the delay, and other regions in the occipitotemporal cortex also showed a significant activation during the delay. Unlike Haxby’s group (Haxby et al., 1995), Courtney’s group concluded that the fusiform and adjacent regions did participate in the maintenance of working memory. They further speculated that this maintenance would

persist only as long as the region was not recruited in the perception of new stimuli.

The results indicating that working memory for faces influences extrastriate regions involved in face processing present interpretive difficulties insofar as none of the studies independently identified the fusiform face areas. Thus it is not clear whether the enhanced activation of the fusiform observed in some working memory tasks occurred in, or was restricted to, face-specific areas. As faces were the only objects seen in each study, it is possible that the activation observed was nonspecific.

Eye and mouth movements

Single-unit studies in monkeys (Perrett, Rolls, and Caan, 1982) and humans (Ojemann, Ojemann, and Lettich, 1992) have identified temporal lobe neurons that respond selectively to faces. Furthermore, Perrett and colleagues have shown that neurons in the superior temporal sulcus are sensitive to the direction of gaze within the face displayed to the monkey (Perrett et al., 1985). Monkeys can accurately discriminate small shifts in gaze direction in photographs, but they suffer significant deficits in this task following surgical removal of the cortex within the superior temporal sulcus (Campbell et al., 1990). Two prosopagnosic patients tested with this task also showed deficits relative to normal control subjects (Campbell et al., 1990).

Our group’s interest in face and eye movements was stimulated by a dissociation between intracranial ERP recordings made from the fusiform gyrus and ERP recordings made from the scalp overlying the posterior temporal area. Intracranial recordings of face-specific N200s showed that full faces evoked larger N200s than those to isolated eyes (Allison et al., 1994b). Scalp recordings, however, revealed that isolated eyes invariably evoked a larger N200 than full faces (Bentin et al., 1996; Taylor, Edmonds, and McCarthy, 1997). This dissociation can be seen in figure 28.5. In fMRI studies, Puce and colleagues (Puce et al., 1995, 1996) had shown a small focus of activation to faces in lateral occipitotemporal cortex in addition to strong fusiform activation (see figure 28.1). Since the scalp electrodes that recorded the larger evoked potential to isolated eyes were placed approximately above the middle temporal gyrus, it was suggested that this part of the temporal lobe might contain a functionally different region for processing dynamic information about eyes. We therefore conducted a fMRI experiment in which subjects viewed moving eyes or moving mouths within an otherwise stationary face, or movements of check patterns that occurred in the same spatial location as the eyes or mouth (Puce et al., 1998). Throughout all stimulus conditions, a moving

FIGURE 28.5 A comparison of ERPs evoked by full faces (solid line) and isolated eyes (dashed lines) illustrating the different pattern of results reported for recordings from the ventral occipitotemporal brain (Allison et al., 1994b) and from scalp electrodes overlying the posterior temporal scalp (Bentin et al., 1996; Taylor et al., 1997). The ERPs on the left were obtained in a single patient from a site on the fusiform gyrus identified as face-specific in a series of screening tasks using faces

and nonface objects (see figure 28.2). Here full faces evoke a larger N200 than do isolated eyes or other face components. The recordings on the right were obtained by Taylor and collaborators (1997) and represent the average response from the right posterior scalp (T6) of 20 subjects viewing the identical stimuli. Here eyes consistently evoke a larger N200 than do full faces. The ERPs to full faces are also earlier in latency than those recorded from the occipitotemporal region.

radial pattern was presented in the background in an attempt to control for the effect of movement per se. Eye and mouth movements, but not the moving check pattern, activated a bilateral region centered in the posterior superior temporal sulcus. The region was anterior to that activated by the moving radial background, which primarily activated the posterior-temporal-occipital fossa and the lateral occipital sulcus—a region corresponding to area MT/V5.

It is notable that the moving eyes and mouth did not activate the fusiform face area. On the basis of neurological lesions, Campbell, Landis, and Regard (1986) demonstrated a double dissociation between face recognition and the ability to lipread. The results of Puce's group suggest, therefore, that the region within the superior temporal sulcus may be both preferentially involved in the perception of gaze direction and mouth movements and related to nearby regions involved in the perception of biological motion.

Emotional expression

Appropriate social communication is dependent upon the correct perception and interpretation of nonverbal cues such as the tone of voice, the emotional expression of a face, and the direction of gaze that both signifies at-

tention and directs the emotional expression to its target. Cross-cultural studies have demonstrated that discrimination among different facial expressions of emotion is universal (for review, see Ekman, 1993; Ekman and Friesen, 1971). Deficiencies in the analysis and/or discrimination of facial expressions have been reported in several psychiatric and neurological disorders such as schizophrenia (Archer, Hay, and Young, 1994; Cutting, 1981), autism (Hobson, Ouston, and Lee, 1988), and Parkinson's disease (Jacobs et al., 1995). Within the physiological literature concerning the perception and analysis of face expression, two issues have been emphasized: whether separate neural regions subserve processing for face identity and facial expression, and whether the analysis of different facial expressions involves different brain structures or shows different patterns of hemispheric activation.

Some prosopagnosic patients can accurately identify the emotional expression of a face but cannot identify the face (e.g., Sergent, 1993). Differences in the pattern of neuropsychological findings have suggested that processing for facial identity and that for facial expression involve different neural pathways (Adolphs et al., 1996; Bowers et al., 1985; Bowers and Heilman, 1984). For example, Bowers and Heilman (1984) reported a patient with a right posterior lesion who could neither

name emotions depicted in pictures of faces nor point to examples of emotional expressions. Humphreys and colleagues (Humphreys, Donnelly, and Riddoch, 1993) reported a patient with relatively good performance in facial identification but poor performance in judging emotional expression. Rapcsak and colleagues (Rapcsak, Comer, and Rubens, 1993; Rapcsak, Kaszniak, and Rubens, 1989) report two patients with damage to the right inferior and middle temporal gyrus who demonstrated selective deficits in matching emotional expressions with their names, and with pointing to pictures of faces depicting particular emotions. Single-unit recordings from the superior and middle temporal gyrus in the right temporal lobe of patients undergoing awake craniotomy showed a significant proportion of cells to be responsive when patients were engaged in face matching and the labeling of facial expression (Ojemann, Ojemann, and Lettich, 1992). Bauer (1986) suggested that two distinct neural pathways are involved in the processing of faces—a ventromedial route responsible for processing underlying overt recognition of faces, and a dorsal route initially involving lateral temporal cortex and projecting to parietal lobe and cingulate gyrus related to emotional processing.

Studies of focal brain damage in humans have reported an overall right hemisphere role in processing facial expression (Adolphs et al., 1996; Bowers et al., 1985). For example, Adolphs and colleagues (1996) investigated the neural systems involved in recognizing facial emotional expression in 37 subjects with focal brain lesions to the left or right hemispheres. Subjects with left hemisphere lesions showed no impairment in processing facial expression. Subjects with right hemisphere lesions were impaired in recognizing certain negative emotions, such as the recognition of fear, but not in the recognition of happy expressions. Within the right hemisphere, the regions corresponding to greatest impairment were the inferior parietal cortex and the mesial anterior intracalcarine cortex. Young and colleagues (1993), however, reported four patients deficient in recognizing facial emotion with unilateral left hemisphere lesions.

Behavioral studies using tachistoscopic displays of lateralized faces have shown a similar inconsistent pattern of results regarding laterality. Many show a left visual field/right hemisphere advantage for processing facial expression (e.g., Ley and Bryden, 1979; Wedding and Cyrus, 1986); but this result has been reported to occur for negative expressions only (Moretti, Charlton, and Taylor, 1996), positive expressions only (Duda and Brown, 1984), or not at all (Stalans and Wedding, 1985). One influential model posits that negative emotions are predominantly processed within the right hemisphere

while positive emotions are processed by the left hemisphere (see Davidson, 1992).

Several neuroimaging studies have investigated the neural systems involved in processing facial emotions. Sergent and colleagues (1994) conducted PET studies to investigate whether differences in processing face identity and emotional expression involved different brain regions. Sergent had two active conditions—a famous-face discrimination task, and a face emotion discrimination task with unfamiliar faces. The right fusiform gyrus was activated by face identity but not by face emotion, suggesting that this area did not participate in the analysis of face emotion. The right middle occipital gyrus was, however, activated by the face emotion task, consistent with the right posterior dominance seen for both positive and negative emotions in the study by Gur, Skolnick, and Gur (1994).

Dolan and colleagues (1996) conducted a face-delayed match-to-sample task with a 45-s retention interval and compared conditions involving happy or neutral expressions. Compared to neutral, the positive expressions activated the left inferior frontal gyrus, the left anterior cingulate gyrus, the right fusiform gyrus, and the thalamus. George and colleagues (1993) conducted a task in which subjects were asked to match pictures of faces based on emotional expression or identity. When comparing emotion to identity matching, significant activation was observed bilaterally in the inferior frontal gyri and in the right anterior cingulate.

These results demonstrate a difference in activation related to facial expression processing, but offer little consistency among the structures activated. Two studies obtained activation of the anterior cingulate (although predominantly in different hemispheres) and in the inferior frontal gyri (Dolan et al., 1996; George et al., 1993). One study found that emotional face expression activated the right fusiform gyrus (Dolan et al., 1996), one explicitly found no fusiform activation (Sergent et al., 1994), while the third found no activation of the fusiform even when comparing faces to a spatial control task (George et al., 1993).

Single-unit studies in the amygdala of monkeys (Leonard et al., 1985) and humans (Heit, Smith, and Hargren, 1988) have shown that the amygdala is responsive to faces. Several recent neuropsychological studies have strongly implicated the amygdala in the processing of emotional expression. Adolphs and colleagues (1994, 1995) reported a subject with a genetic disorder resulting in selective bilateral amygdala damage. This patient had greatly impaired judgment in the recognition of fearful expressions—a deficit not found in their patients with unilateral amygdala lesions. The patient with bilateral amygdala damage had no difficulty in recognizing faces

and could skillfully draw all facial expressions except fearful expressions. In a subsequent study, Adolphs and colleagues demonstrated that three subjects with bilateral amygdala damage were markedly deficient in their ability to judge the trustworthiness and approachability of faces, particularly with faces ranked as negative by subjects with unilateral amygdala damage and by normal controls (Adolphs, Tranel, and Damasio, 1998). In contrast, the bilateral amygdala subjects had no difficulty in discriminating faces or in making social judgments on the basis of verbal descriptions. On the basis of these results, it was suggested that the amygdala is an important component of a neural system that uses facial expression to retrieve socially relevant knowledge. In addition, Scott and colleagues (1997) reported that bilateral amygdala lesions also impair judgments concerning the emotional intonation of auditorily presented sentences, particularly with regard to fear and anger.

Several recent neuroimaging studies have implicated the amygdala in the processing of emotions and emotional stimuli (Drevets et al., 1992; Irwin et al., 1996; Ketter et al., 1996; Schneider et al., 1997) and in the analysis of facial expression. Breiter and colleagues (1996) reported a fMRI study in which fearful faces activated the amygdala bilaterally when compared to blocks of neutral faces. In a second experiment using a region of interest analysis, Breiter's group again found left amygdala activation for fearful expressions and for happy faces. They observed a somewhat differential pattern of activation for these different emotions within the amygdala, and found that neutral faces also showed some amygdala activation compared to nonface controls. The left amygdala showed rapid habituation for emotional expressions, and the right amygdala was not significantly activated by any face stimuli.

In two PET studies, Morris and collaborators (1996, 1998) showed greater left amygdala activation to fearful faces than to happy faces. The left amygdala and insular cortex showed increasing activation to increasing intensity of fearfulness. As before, the right amygdala showed no activation to faces. Morris also noted that the left amygdala increased its activity as the intensity of happy faces was decreased, suggesting that the left amygdala responds to happy faces by decreasing its activation below baseline. Both Breiter (Breiter et al. 1996) and Morris (Morris et al. 1996, 1998) showed that facial emotion also affected processing in extrastriate regions, suggestive of a backprojection or neuromodulatory influence from the amygdala.

Whalen and colleagues (1998) used fMRI to study unconscious emotional processing in the amygdala. Subjects were presented with happy or fearful faces for 33 ms, whereupon they were immediately shown a face de-

picting a neutral expression. As a result of this backward-masking procedure, eight of the ten subjects reported seeing only the neutral expressions. Despite the lack of conscious awareness, activation of the amygdala was higher for the masked fearful faces, and lower for the masked happy faces, than for a fixation control. Activation was restricted to the amygdala, but was bilateral and habituated after two runs.

Morris and colleagues further explored the role of conscious and unconscious processing of facial expression by the amygdala and its influence upon the laterality of the activation (Morris, Ohman, and Dolan, 1998). Angry faces previously paired with aversive white noise bursts evoked activity in the right amygdala when a backward mask (a face with neutral expression) was applied and the patient was unaware of the angry face. However, when the angry face was unmasked and consciously perceived, only the left amygdala was activated.

The studies to this point have implicated the amygdala in the analysis of negative, primarily fearful, facial expression. Phillips and collaborators (1997) compared fMRI activations to two negative emotions—fear and disgust—using mildly happy faces as controls. Two intensities of each emotion were tested while subjects performed a gender discrimination task in which facial expression was irrelevant. Consistent with the studies reviewed above, medium-intensity fearful faces evoked activity in the left amygdala and left insula. Disgust did not activate the amygdala; rather, the most prominent activation was found in the right anterior insula, where the level of activation increased with the intensity of the disgusted expression. It was suggested that the facial expression of disgust is closely linked to the region activated by noxious gustatory stimuli. Perception of disgust in another individual was hypothesized to have a selective evolutionary advantage.

The neuroimaging and neuropsychological studies reviewed above clearly dissociate the processing of facial expression from facial identity and strongly implicate the amygdala in the processing of emotional expressions. Across studies, the most consistent amygdala activation was obtained for fearful expressions, with less consistent results noted for positive or happy expressions which may, in fact, reduce amygdala activation (Morris et al., 1996). Overall, the left amygdala was more activated by emotional expressions than the right amygdala, although this may be related to the subject's conscious awareness of the emotional expression (Morris, Ohman, and Dolan, 1998). The role of the amygdala in processing fearful expressions is particularly interesting given its demonstrated role in fear conditioning. In that regard, the selective response of the insula for expressions of disgust (Phillips et al., 1997) is noteworthy

given the putative role of that brain region in taste. These results suggest that the perception of different emotions may be closely related to specific neural systems involved in behaviors relevant to that particular emotion.

Summary and conclusions

The studies reviewed strongly implicate the ventral occipitotemporal cortex, and particularly the fusiform gyrus, in the initial processing of faces. Bilateral activation was obtained in almost all studies, but the right hemisphere activation was consistently stronger and spatially more extensive. Faces activated a larger region of ventral occipitotemporal cortex when there were no other objects in the visual field than when the field contained other objects. This suggests that faces may be processed by both face-specific and general object recognition systems. Face-specific cortex therefore represents a more focal region of activation than indicated in most PET and fMRI studies. The face-specific regions were not activated by exemplars of other stimulus categories, including nonface body parts, even when within-category discriminations were required by the task. The electrophysiological data establish that faces are differentiated from other stimulus categories by 200 ms, and that this processing is relatively insensitive to habituation. Taken together, these results suggest the presence of a neural module in fusiform gyrus that responds in a fast and obligatory manner to faces. Whether this putative module is hardwired from birth or develops from long experience with faces is undecided by these data.

The modularity of face processing in the fusiform gyrus is challenged, however, by several studies reporting enhanced activation within the ventral occipitotemporal region as a consequence of top-down processing involving attention (Haxby et al., 1994; Wojciulik, Kanwisher, and Driver, 1998), working memory (Courtney et al., 1996, 1997), and analysis of emotional expression (Breiter et al., 1996; Morris et al., 1998). However, with one exception (Wojciulik, Kanwisher, and Driver, 1998), these studies did not independently identify face-specific cortex within the ventral extrastriate regions. Moreover, these studies provide no information about when the top-down modulation may have occurred. It may be that initial face processing, as reflected by N200, is relatively insensitive to top-down influence, but that later processing at N200 or more anterior sites further engages the face-specific fusiform areas and modulates their activity.

Tasks emphasizing memory for faces differentiated posterior fusiform and more anterior activation of the medial temporal lobe, including the parahippocampal

gyrus and hippocampus. The dependence of activation within the medial temporal lobe for face encoding and face retrieval was uncertain and might be differentiated by hemisphere. Taken together, the neuropsychological and neuroimaging data suggest a ventral pathway for face processing where faces are extracted from the visual scene and differentiated from other objects in the posterior and mid-fusiform gyrus, and where the recognition of particular faces is performed in the anterior and medial temporal lobe.

A second pathway for face analysis may occur in more dorsal regions and involve the middle occipital and temporal gyri, and the superior temporal sulcus where activity may be related to the extraction of dynamic features from faces, such as eye movements and mouth movements. The lack of activation in the ventral face areas by moving eyes and mouths suggests that these dorsal regions were activated in parallel to the ventral face regions. The targets of this putative dorsal pathway are unknown. Given the role that dynamic changes in eye and mouth position play in facial expression, we speculate that the amygdala may receive input from this region to integrate the face with its social context.

29 Physiological Basis of Timbre Perception

SHIHAB A. SHAMMA

ABSTRACT Speech, music, and other complex sounds are characterized by their pitch, timbre, loudness, forms of modulation, and onset/offset instants. These descriptions of sound quality have a close relationship to the instantaneous spectral properties of the sound waves. Physiological, psychoacoustical, and computational studies reveal that the central auditory system has developed elegant mechanisms to extract and represent this spectrotemporal information. For instance, the primary auditory cortex (A1) employs a multiscale representation in which the dynamic spectrum is repeatedly represented in A1 at various degrees of spectral and temporal resolution. This is accomplished by cells whose responses are selective to a range of spectrotemporal parameters such as the local bandwidth and asymmetry of spectral peaks, and their onset and offset transition rates. These findings are reviewed here, together with their functional implications and applications in sound analysis systems, and the experimental methods developed to collect and interpret them.

In a complex acoustic environment, several sound sources may simultaneously change their loudness, location, timbre, and pitch. Yet, like many other animals, humans are able to integrate effortlessly the multitude of cues arriving at their ears, deriving coherent percepts and judgments about the attributes of each sound source. This facility to analyze an auditory scene is conceptually based on a multistage process in which sound is first analyzed in terms of a relatively few perceptually significant features (the alphabet of auditory perception). Then higher level integrative processes organize and group the extracted features according to specific context-sensitive rules (the syntax of auditory perception).

Much has been learned in recent years about the initial and final stages of this process. Physiological experiments have revealed the neural representations of sound in the early stages of the auditory pathway, and the elementary features that underlie the perception of such attributes as timbre and location (Young and Sachs, 1979; Sullivan and Konishi, 1986; Knudsen, 1984; Blackburn and Sachs, 1990). Similarly, psychoacoustical investigations have shed considerable light

on the way we form and label sound images based on relationships among their physical parameters (Bregman, 1978). However, the crucial transitional stages between the physiological representations and their perceptual correlates remain mysterious and subject to considerable study and debate.

To illustrate these arguments, consider the role of pitch and timbre percepts in grouping the components of a complex sound such as the vowels /a/ and /i/ in figure 29.1, where /a/ represents the vowel sound as in /bat/ and /i/ represents the vowel sound as in /beet/. Each vowel here consists of many harmonics of a fundamental frequency—approximately 95 Hz (for /i/) and 170 Hz (for /a/)—which corresponds to the *pitch* of the vowel heard in each case. The *timbre* of the vowels is broadly defined by the American Standards Association as that “attribute which is not pitch or loudness,” a definition that reflects the difficulty in specifying its physical correlates (Plomp, 1976). The most salient of such correlates is the shape of the spectral envelope (or profile) and its dynamics. Thus, to first-order, a particular vowel (e.g., /a/ in figure 29.1) preserves its perceptual identity if the envelope of its spectrum remains stable, regardless of the nature of the underlying spectral components. For

FIGURE 29.1 Schematic of acoustic spectra of speech vowels. The harmonic structure of the spectrum is represented by the equally spaced components on the linear frequency axis. The fundamental frequency is the lowest component, and is equal in this case to the frequency separation between the harmonics. Harmonic series give rise to a pitch percept equal to the fundamental (note that pitch of the vowel /a/ in the figure is about twice as high as that of /i/). The envelope of the spectrum (also called the profile) is the primary cue responsible for its timbre. Different vowels are distinguished by their distinctive profiles, especially the location and shape of the spectral peaks (also called the formants).

SHIHAB A. SHAMMA Center for Auditory and Acoustic Research, Institute for Systems Research, Department of Electrical Engineering, University of Maryland, College Park, Md.

instance, it is perceived as being voiced with a certain pitch if the components are a harmonic series, and perceived as whispered if the underlying spectrum is noisy. Timbre is also determined by the dynamics of the spectral envelope, as in distinguishing between a piano and violin based on the speed of their rise (or onset) and decay times (Plomp, 1976).

Numerous experimental studies have demonstrated that if the two vowels in figure 29.1 are heard simultaneously, they could be segregated based solely on their spectral profiles. However, the segregation is significantly easier when the pitch of the vowels is different, or when their harmonic components have different onset times. These cues (and many others) accumulate to facilitate the sorting and grouping of different sound sources in a complex acoustic environment (Mellinger and Mont-Renaud, 1995; Lyon and Shamma, 1995). To make use of these percepts in acoustic scene analysis, the auditory system must extract and represent the underlying stimulus features in its neural response patterns. To illustrate these neural processes and representations, we focus in this review on the perception of timbre—specifically, on the neural representation of its most important physical correlates in the peripheral and cortical stages of the auditory system. We begin by summarizing the latest findings on how the spectral profile shape and its dynamics are encoded at various levels of the auditory system. We then discuss how the emergence of invariance to certain features may directly reflect our timbre perception, asking how these features might link with higher level analysis and rules whose exact physiological bases remain obscure. In addition, we highlight an important principle of sensory coding—that of multiscale or multiresolution decomposition, which operates in the auditory system both in the early and central stages of analysis and along the spectral and temporal dimensions of the stimuli.

Multiscale analysis of the acoustic spectrum in the early auditory stages

Sound signals undergo a series of complex transformations in the early auditory system, as illustrated in figure 29.2. These stages convert the acoustic spectrum of the stimulus into an internal representation that we call the *auditory spectrum*. The biophysics of these operations is rather elaborate (for a detailed review, see Deng, Geisler, and Greenberg, 1988; Greenberg, 1988; Shamma et al., 1986). Briefly, sound pressure waves impinging upon the eardrum cause vibrations that are transmitted to the fluids of the cochlea via the ossicles of the middle ear. These vibrations induce pressure differences across the basilar membrane, which in turn produce mechanical

displacements whose amplitudes peak at different locations along the cochlea depending on the frequency of the stimulus. For high frequencies the maximum response occurs near the base of the cochlea, while for lower frequencies it occurs near the apex. In this way, the spatial axis of the cochlea may be associated with a *tonotopically* (frequency) ordered axis.

One simple way to visualize the response characteristics of the basilar membrane is to associate each point on it with a frequency-selective (or bandpass) filter, i.e., to model the basilar membrane as an ordered bank of filters. These filters are relatively broadly tuned and significantly asymmetric in shape, with a steep roll-off on their high-frequency sides. The center frequency of each filter is called the characteristic frequency (CF). For much of the audible frequency range (roughly above 500 Hz) the filters' bandwidths are linearly proportional to the CF; i.e., the filters have constant tuning over most of the cochlear length. This property implies that (1) the CFs of the filters are logarithmically mapped along the tonotopic axis, and (2) the cochlear in effect performs a frequency decomposition of the sound signal known as an affine wavelet transform (Yang, Wang, and Shamma, 1992). In this analysis, the increasing bandwidths toward higher CFs imply progressively coarser absolute frequency resolution (but a constant relative resolution). From a perceptual point of view, this multiresolution (also called multiscale) transformation offers a compromise between the temporal and spectral dimensions. Thus, higher (lower) frequencies analyzed by smaller (wider) time-windows facilitate both a good temporal resolution of transient acoustic stimuli in the higher frequency bands and spectral resolution of narrow peaks in the lower frequency bands.

The cochlear filter outputs are then transduced into intracellular receptor potentials by a dense, topographically ordered array of sensory hair cells. For frequencies up to 3–4 kHz, the receptor potentials reflect faithfully the detailed temporal fine structure of the filter outputs. For higher frequencies, only the short-term power in the filter outputs is preserved (Sachs and Young, 1979). The receptor potentials also exhibit a limited dynamic range of about 30–40 dB due to a hair cell nonlinearity. Beyond this level, the hair cell is driven into saturation and the receptor potentials appear heavily compressed. Finally, the receptor potentials are converted into stochastic trains of electrical impulses (firings) that travel down the fibers of the auditory nerve which project to the cochlear nucleus, the first station of the central auditory system. There, recipient neurons in the cochlear nucleus reconstruct estimates of the receptor potentials by effectively computing the ensemble averages of activity in locally adjacent fibers (Shamma, 1989).

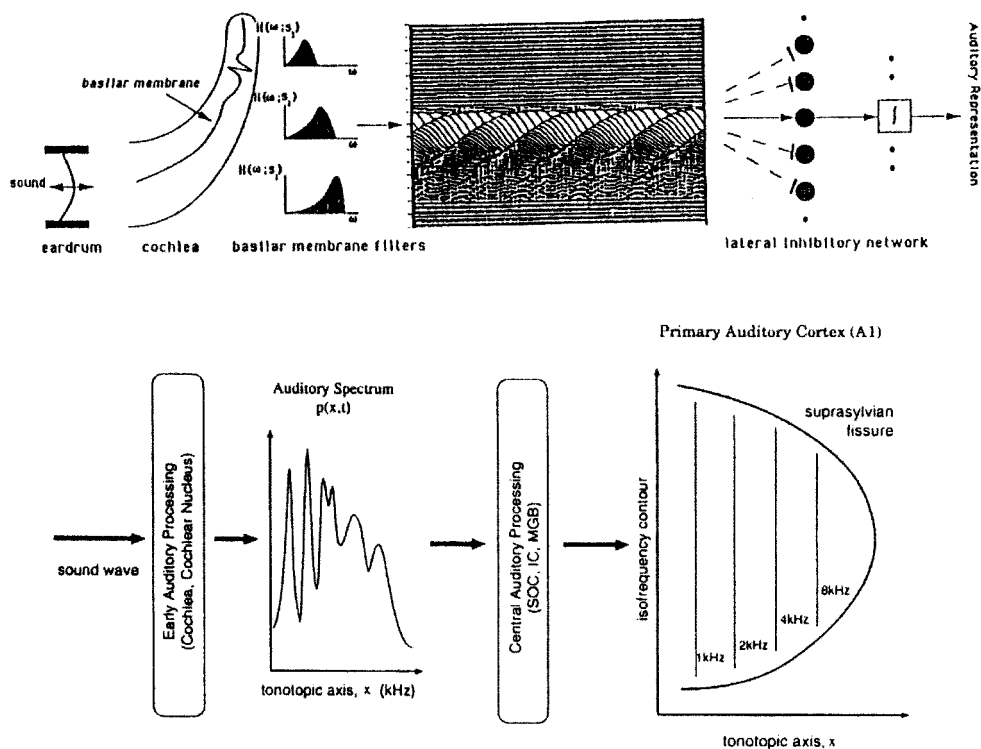

FIGURE 29.2 Overview of some of the auditory transformations of the acoustic signal. Top: Schematic illustrating the major processing stages in the early auditory system. Sound initiates traveling-wave displacements on the basilar membrane. Displacements at each point are modeled as bandpass filters centered on a specific frequency, with high frequencies near the entrance (base) of the cochlea and lower ones towards the apex. The displacements are transduced into neural activity in a topographically ordered array of fibers (the auditory

nerve). The response patterns are then conveyed to the cochlear nucleus where it is hypothesized that lateral inhibitory networks extract an enhanced auditory representation of the sound spectrum (Shamma et al., 1986; Shamma, 1985a,b). Bottom: Overview of the auditory nervous pathway, which includes the cochlea, cochlear nucleus, superior olivary complex (SOC), lateral lemniscus, inferior colliculus (IC), the medial geniculate body (MGB), and the tonotopically organized primary auditory cortex and other cortical fields.

Responses of the auditory nerve contain information about all attributes of the sound stimulus, including its timbre, pitch, and other spatial and temporal characteristics. Presumably, various networks and pathways are involved at this point in estimating and encoding the necessary features associated with each of these attributes. Specifically, it has been demonstrated physiologically that the extraction of the spectral profile from the auditory nerve responses occurs at this stage by a population of stellate cells in the anteroventral portion of the cochlear nucleus (AVCN) (Blackburn and Sachs, 1990). The exact network topology that gives rise to this estimate remains uncertain. One possible scheme involves lateral inhibitory interactions which effectively sharpen the responses across the auditory nerve fiber array or, equivalently, decorrelate the activity across the array (Shamma, 1985). Anatomical and physiological support for this lateral inhibition in the cochlear nucleus is discussed in (Shamma, 1989).

The short-time averaged outputs from such a network closely resemble the spectral profile of the stimulus with few important modifications. They include a sharpened representation of the spectral peaks relative to the valleys, and a suppression of background noise that closely resembles the masking phenomenon observed in psychoacoustical experiments (Moore, 1986; Wang and Shamma, 1994). Figure 29.3 illustrates such an auditory spectrum computed for a full sentence, */come home right away/*, using a computational model of the early auditory stages (available upon request from <ftp://zikr.isr.umd.edu/speech/nsltools.tar.gz>). Note that for a dynamic spectrum like that of a sentence (as opposed to that of static vowels as shown in figure 29.1), changes or modulations in the spectral profiles in time occur at relatively slow rates (on the order of 10–20 Hz), reflecting the phonetic and/or syllabic structure of the utterance. These modulation rates are typical of music, speech, and many natural sounds, and are well matched to the temporal response sensitivity of higher auditory centers.

FIGURE 29.3 The auditory spectrogram of the sentence /*come home right away*/ generated by a computation model of the

early auditory stages. Approximate assignments of the different phonemes are also indicated.

Multiscale representation of the acoustic spectrum in the auditory cortex

The spectral pattern extracted early in the auditory pathway (the cochlea and cochlear nucleus) is relayed to the primary auditory cortex (A1) through several stages of processing, as shown in figure 29.2 (Webster, Popper, and Fay, 1992). Therefore, A1 responses integrate all influences from preceding nuclei, which are likely involved in a host of other perceptual tasks such as binaural localization and pitch estimation. As in other sensory systems, the auditory pathway is topographically (tonotopically) organized all the way up to the A1. Thus, when tested with single tones, neurons along this pathway are found to be selective to a range of frequencies around a “best frequency” (BF). Within this range, responses change from excitatory to inhibitory in a pattern that varies from one cell to another in its width and asymmetry around the BF. This response pattern is usually called the response area, or response field (RF), of the neuron and is illustrated in figure 29.4. The RF is strictly analogous to the notion of a receptive field in retinal and other visual cells, where it usually denotes the incidence angles of the light, or, equivalently, the portion of the sensory epithelium which, when stimulated, induces excitatory and/or inhibitory responses in the cell. In the auditory system, the RF is defined with respect to the tonotopic axis (which effectively labels the sensory epithelium).

It is clear that the detailed shape of a neuron’s RF largely dictates its responses. Consequently, the search for a neural representation of a particular sound attribute

can be achieved through measurements of a wide variety of RFs, coupled with an interpretation of these RFs in terms of their selectivity to meaningful features of that attribute. As an example, consider the multiscale representation of the spectral profile shown in figures 29.5 and 25.6 and thought to exist in A1 based on extensive neurophysiological data collected over the last decade. Here, the auditory spectrum is repeatedly represented at various degrees of resolution. The basic outlines of this representation are described for stationary spectra first (the vowel /*a*/) (figure 29.5; see color plate 17), and then for full dynamic spectra (figure 29.6; see color plate 18).

In figure 29.5A, the auditory spectral profile of the vowel /*a*/ is shown as would be presumably extracted at the cochlear nucleus. Several versions of this profile

FIGURE 29.4 Schematic of response fields (RFs) of two auditory units defined against the tonotopic axis. In each case, the unit is excited around a particular “best frequency” (BF). The excitatory region of responses is surrounded by other frequencies to which the cell is inhibited (dark regions). The unit to the left has a relatively broad bandwidth (wide RF), and the inhibitory sidebands are asymmetric. The unit to the right is narrowly tuned around the BF, and has the opposite asymmetry of inhibition around its BF.

FIGURE 29.5 Multiscale representation of spectral profiles in the auditory cortex. (A) The auditory spectral profile of a naturally spoken vowel /a/. (B) The cortical representations of the spectral profile of the naturally spoken vowel /a/. The tonotopic axis is given in kilohertz. The ordinate is the scale axis (fine to coarse from top to bottom), which reflects the bandwidth of the RF; the axis is labeled by the ripple frequency to which the RF at each scale is most responsive. The strength of the response is indicated by the intensity of the color. For illustrative reasons, the strength of the response at several scales is also shown by the solid profiles superimposed upon this figure. The fine structure of the spectral profiles is seen only at the highest scales, whereas its coarse overall outline appears at the lower scales. Color encodes the local asymmetry of the most

responsive RF: Green indicates that the most responsive RF at this location is symmetric, red (blue) indicates RFs that are odd-symmetric, and purple is an inverted RF. Therefore, color provides a description of the local energy distribution in the spectrum. For example, the tonotopic locations at which the spectrum is locally symmetric (green) closely reflect the positions of the peaks in the auditory spectrum; red (blue) indicates whether the local spectral slope is rising (falling) or if the nearest spectral peak is at a higher (lower) frequency. (C) A schematic of the three RF organizational axes that give rise to the cortical representation: the best frequency (tonotopic axis), the bandwidth (the scale axis), and the asymmetry. Along each axis, the RF changes its shape gradually as indicated.

are displayed in figure 29.5B with various degrees of resolution from the coarsest (smoothest or the most averaged) at the bottom to the finest (most detailed) at the top. Thus, the spectral peaks that dominate this profile—e.g., the resolved harmonics in the low-frequency region (<1 kHz) and the peaks of the overall spectral envelope (called formants, at approximately 700, 1200, and 2700 Hz)—are explicitly analyzed in the cortical representation in terms of their local symmetry and bandwidth. For instance, the formants are relatively broad in bandwidth and thus are represented in the coarse or low scale regions (<1 cycle/octave). In contrast, the fine structure of the harmonics is visible only

at high scales (>1 cycle/octave). One way such patterns of cortical activation can be generated is through repeated layers of tonotopically ordered neurons with RFs of different bandwidths, in effect forming a two-dimensional sheet of A1 neurons (Mendelson and Schreiner, 1990).

The spectral representation in A1, however, is more complex, with a third dimension encoding the local shape (or asymmetry) of the spectrum. This axis is indicated by the color of the most responsive neurons at each CF. Green, red, and blue represent units most responsive to a local spectral profile that is distributed evenly around, skewed mostly above, or skewed mostly

A**B****C**

FIGURE 29.6 A1 multiscale analysis of auditory spectra along the spectral and temporal dimensions. (A) Schematic of spectrotemporal response fields (STRF) in A1. The STRF is intuitively an extension of the notion of RF to the temporal dimension. Light (dark) shaded regions indicate excitatory (inhibitory) regions. The left panel illustrates a broadly tuned, dynamically agile, upward sensitive STRF while the right panel illustrates STRF with the opposite properties. The parameters (0.5 cycles/octave and 16 Hz, 4 cycles/octave and 4 Hz) indicate the density and velocity of the most effective ripple spectrum for these units (see also figure 29.7). (B,C) Each panel shows the auditory spectrogram of the sentence /come home right away/ (shown earlier in figure 29.3) as represented by the activity of units with directionally selective RFs [downward-sensitive STRFs in (B); upward-sensitive in (C)], with progressively finer spectral resolution (left to right) and increasingly rapid temporal resolution. The insets to each panel depict the STRF used to generate the spectrogram. Colors represent the phase of the response (exactly as in figure 29.5); the intensity of the color is proportional to the strength of the response.

below their CFs, respectively. RFs can easily achieve this response selectivity with inhibitory sidebands of different asymmetries, as illustrated in figure 29.4 (Shamma et al., 1993). In summary, the RFs needed to generate the above-described A1 responses must continuously vary along the three axes shown in figure 29.5C: tonotopic, bandwidth, and asymmetry.

Natural acoustic spectra are rarely stationary, but rather evolve, reflecting the changing characteristics of the source—the succession of different phonemes in a sentence or of different instruments in a symphony for example. Figure 29.3 shows the auditory spectrum of the sentence /come home right away/ over approximately one second. Note the rapid onsets and offsets in the energy of the formants, especially near stop consonants such as /c/ and /t/. As with stationary vowel spectra (figure 29.5), the “auditory spectrograms” are represented in A1 in multiple resolutions, as illustrated in figure 29.6. These representations imply cortical RFs that are defined not only with respect to the spectral (tonotopic) axis, as in figure 29.4, but also along a temporal dimension as shown in figure 29.6A. Spectrotemporal RFs (STRFs) may vary in their spectral BFs, bandwidths, and asymmetry, and also in their temporal agility and directional selectivity. For instance, the STRF on the left is relatively broadly tuned (about 2 octaves), dynamically agile, and exhibits an upward directional selectivity. By comparison, the STRF on the right is narrowly tuned spectrally, downward sensitive, and is relatively slow.

A1 units have indeed been found to vary along these multiple dimensions, exhibiting spectral bandwidths from 0.5 to 2 octaves, temporal selectivities that range

from rapid responses (over 16 Hz) to very slow (under 4 Hz), and directional sensitivities to upward, bidirectional, and downward moving spectral energy. Populations of these different kinds of STRFs can support a spectrotemporal multiscale representation of the spectrograms as shown in figure 29.6B,C for the same sentence as in figure 29.3. Each panel here displays the spectrogram viewed at a certain spectral and temporal resolution. Also shown to the left of each panel is the hypothetical STRF of the unit population that generates the activity seen. For instance, units in upper panels (figure 29.6B) are upward-sensitive, and hence exhibit only upward-sweeping spectral energy; the opposite is true for the lower panels (figure 29.6C). Panels B1 and C3 are broadly tuned but temporally rapid, thus highlighting spectrally coarse events in the spectrograms; panels B4 and C2 encode the opposite features (spectrally fine, temporally slow receptive fields). These two pairs of representations are polar opposites of each other perceptually, the latter pair emphasizing the physical correlates of pitch and long vowels (the harmonic peaks and their slow change in time), and the former emphasizing the spectral features and dynamics usually associated with the perception of consonants.

Physiological foundations of the multiscale representations

The auditory system performs a twofold multiscale analysis in which the acoustic signal is first transformed into the auditory spectrum in the cochlea and cochlear nucleus, followed by a transformation of the auditory spectrum into the cortical representation seen in A1. The physiological foundations of the multiscale analysis in the cochlea are well established and will not be elaborated upon here. Perhaps the most persuasive evidence for it is the logarithmic distribution of frequencies along the tonotopic axis, together with the roughly constant Q filtering of the basilar membrane (Webster, Popper, Fay, 1992).

The cortical multiscale representation is based on extensive recordings in A1 employing a wide range of acoustic stimuli, both natural and artificial, spectrally narrow and broad, species-specific and otherwise (Clarey, Barone, and Imig, 1992; Shamma, 1996). Compared to the auditory periphery, the functional organization in A1 has remained uncertain. In large part, this is attributable to the complexity and nonlinearity of the representation their spectra—even the simplest spectra such as those of a single tone at different sound levels (Phillips et al., 1994; Irvine, 1992). Another complicating factor is the multiple overlapping maps of various

spectral and temporal features discovered along the isofrequency planes of A1 (Versnel, Kowalski, and Shamma, 1995; Calhoun and Schreiner, 1995; Mendelson and Schreiner, 1990; Suga, 1984). Nevertheless, these results have led to several viable hypotheses regarding the way the spectral profile might be encoded in A1 and other auditory fields (Phillips et al., 1994; Wang and Shamma, 1995; Irvine, 1992).

A basic measurement in the experimental validation of all hypotheses is that of the unit response area, defined roughly as the range of tone frequencies and intensities that elicit excitatory or inhibitory responses. Response areas are usually measured using single or multiple tonal stimuli, and are found to vary considerably from one cell to another in their width and asymmetry around the BF (Shamma et al., 1993). While qualitatively useful as predictors of a unit's responses to arbitrary broadband spectra, response area measurements are significantly affected by a host of measurement difficulties and nonlinear factors (Shamma, Versnel, and Kowalski, 1995; Nelken, Prut, and Vaadia, 1994) that render their parameter estimates (e.g., bandwidth and asymmetry) quantitatively uncertain.

To circumvent some of these problems, new techniques have been employed to measure the spectral and dynamic properties of response areas in A1 and potentially other auditory fields and nuclei (Calhoun and Schreiner, 1995; Shamma, Versnel, and Kowalski, 1995). The stimuli and techniques apply linear system theory to measure the response area of cortical units. In one method, the stimuli used are broadband spectra with sinusoidally modulated profiles against the logarithmic frequency axis—also called ripples as shown in figure 29.7. These stimuli are analogous to the drifting gratings used in receptive field measurements in VI and other visual structures (De Valois and De Valois, 1990). By varying the peak density, amplitude, phase, and the drifting velocity of the ripple, one can measure a ripple transfer function. Using an inverse Fourier transform, we can then obtain a spectrotemporal response field (STRF) function that effectively resembles the response area of the unit, as explained in detail in figures 29.8 and 29.9. In another method (shown in figure 29.10), stimuli with random and dynamic spectral profiles are cross-correlated with the responses to extract the STRF (also known as the reverse-correlation method) (Eggermont, 1993). Using these methods, STRFs of hundreds of units in A1 have been measured, mapped, and compared to those obtained from single and two-tone stimuli (Shamma, Versnel, and Kowalski, 1995; Kowalski, Depireux, and Shamma, 1996a,b).

Figure 29.8 illustrates the responses to moving ripples and the way in which they are analyzed. The raster re-

FIGURE 29.7 The ripple spectral profile is shown to the left of the spectrogram. It usually consists of 101 tones equally spaced along the logarithmic frequency axis, spanning 5 octaves (e.g., 0.25–8 kHz). The sinusoidal envelope has a ripple density or frequency Ω , given in cycles per octave. It moves at a constant velocity ω defined as the number of ripple cycles traversing the lower edge of the spectrum per second (hertz). The spectrogram of this moving ripple is shown to the right. Different ripple frequencies, velocities, and direction change the orientation of the sweeps. The ripple in the figure is at $\Omega = 0.4$ cycles/octave, and $w = 4$ Hz.

sponses in figure 29.8A are elicited by a ripple spectrum (0.4 cycle/octave) traveling at a range of velocities ($\omega = 4$ –20 Hz). The amplitude and phase of the synchronized response component at each ω are derived and plotted as the magnitude and phase of the transfer function $T_{\Omega}(\omega)$. Figure 29.8B illustrates the complementary test of the response properties to moving ripples; here, ripple velocity is fixed at $\omega = 4$ Hz while the ripple frequency is increased systematically from 0 to 2 cycles/octave. The responses are analyzed as before, and plotted as the magnitude and phase of the ripple transfer function $T_{\omega}(\Omega)$.

The transfer functions thus measured are valid at one ripple frequency or velocity, as indicated by the subscripts ω and Ω , and illustrated in figure 29.9 (bottom) (see color plate 19). In principle, one must measure the two-dimensional transfer function at all Ω and ω , and for both upward and downward directions of moving ripples. However, it has been demonstrated that for a given direction, these functions remain largely unchanged apart from a scale change (Kowalski, Depireux, and Shamma, 1996a,b). Consequently, for each direction, the temporal and ripple transfer functions can be treated separately (i.e., they are quadrant-separable), and the full transfer function can be assumed to equal the products of the two separate measurements (figure 29.9, middle). To obtain the full STRF, the transfer function is then inverse Fourier-transformed as described in more detail by Simon, Depireux, and Shamma (1998).

Very similar overall STRFs are measured using the reverse-correlation method described in figure 29.10 (see color plate 20). Here, the stimuli consist of combinations

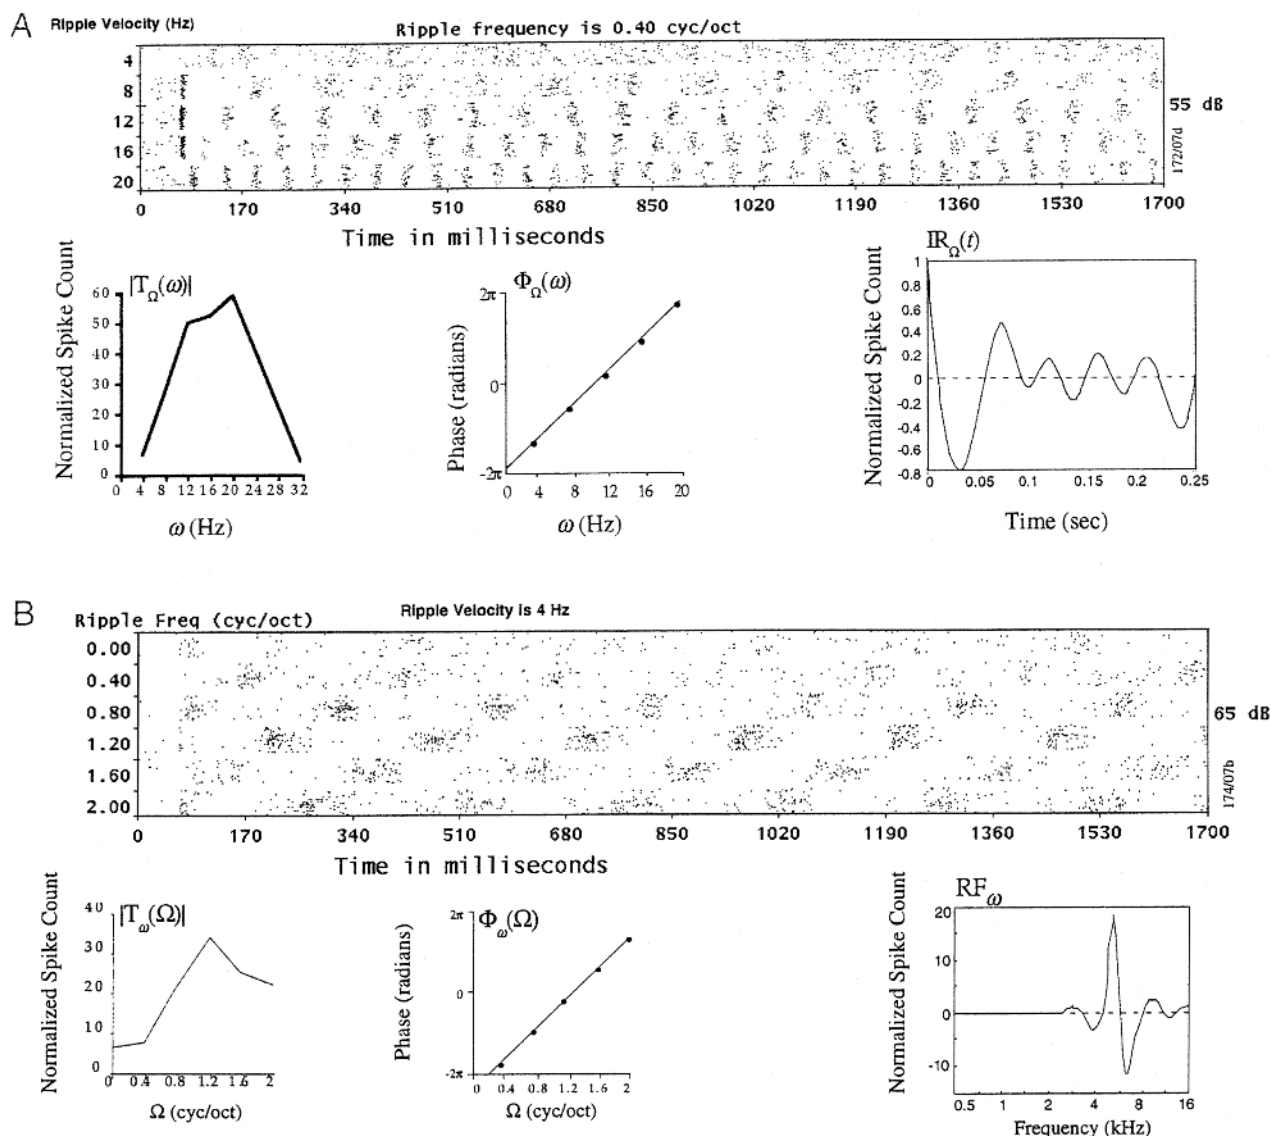

FIGURE 29.8 Analysis of responses to moving ripples. (A) Temporal transfer function. Top: Raster responses to a ripple ($\Omega = 0.8$ cycles/octave) moving at different velocities. The ripple begins moving to the left at 0 ms, and the stimulus is turned on at 50 ms. Bottom: The amplitude $T_{\Omega}(\omega)$ and phase $\Phi_{\Omega}(\omega)$ of the temporal transfer functions are measured from period histograms of the data. The inverse Fourier transform of the transfer function gives the impulse response function of

the cell at a particular ripple ($IR_{\Omega}(t)$). (B) Ripple transfer functions. Top: Raster responses to ripples with different densities all moving at $\omega = 4$ Hz. Bottom: The amplitude $T_{\omega}(\Omega)$ and phase $\Phi_{\omega}(\Omega)$ of the ripple transfer functions are measured from period histograms of the data. The inverse Fourier transform of the transfer function gives the RF of the cell at a particular velocity (RF_{ω}).

of moving ripples with random phases, and all combinations of velocities and ripple frequencies. Using the spike-triggered averaging method (Eggermont, 1993), the spectra most effective in producing spikes are computed and displayed as the STRF shown in figure 29.10C. The similarity between the STRFs obtained from the two measurement techniques confirms the important finding of quadrant separability, since the reverse correlation method does not require this assumption. STRFs measured with dynamic ripples ex-

hibit a variety of shapes, reflecting the selectivity of the underlying transfer functions. For example, some are broadly tuned and asymmetric (as illustrated by the unit in figure 29.11B) while others are relatively narrow and symmetric (figure 29.11A); some are relatively rapid in time (figure 29.9, top; figure 29.11A), and others are slow (figure 29.11B) (Simon, Depireux, and Shamma, 1998). These varied types of STRFs are exactly what are needed to generate the multiscale spectrotemporal representations described earlier.

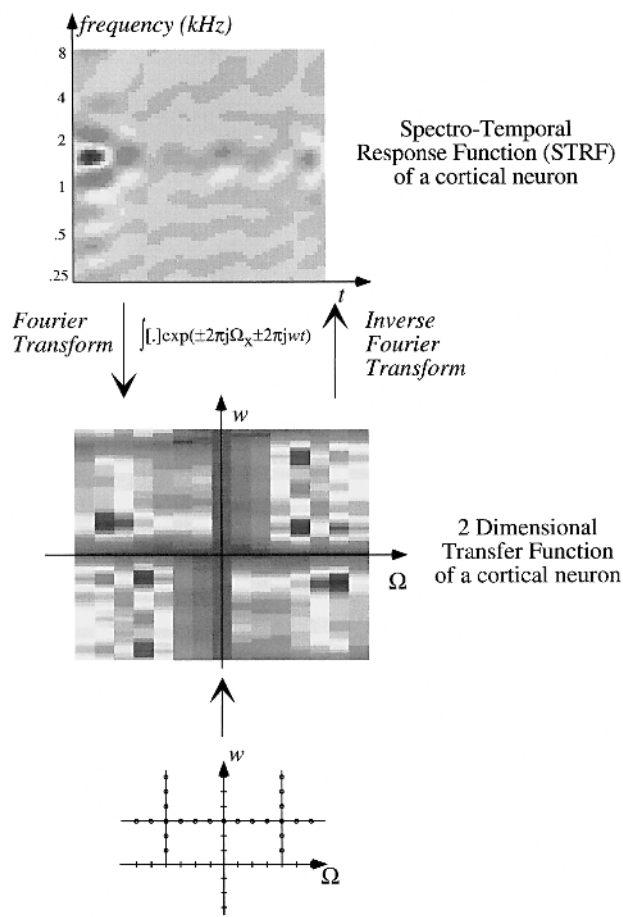

FIGURE 29.9 Computing the full STRF assuming separability. Bottom: The magnitude and phase (not shown) of the two-dimensional transfer function measured as in figure 29.8. Note that measurements are obtained at just one ω and Ω . Middle: Assuming separability, the full transfer function is computed from the product of the two cross sections measured at ω and Ω . Top: The STRF is computed from a two-dimensional inverse Fourier transformation of the transfer function. All colors here indicate the strength of the response. Red (blue) represent the excitatory (inhibitory) fields of the RF.

The ripple analysis techniques assume that the responses to such broadband stimuli are substantially linear in character. The most important correlate of linearity is the *superposition principle*, which implies that responses to combinations of ripples are linearly additive and can be predicted from the responses to single ripples. These assumptions have been verified by successfully predicting responses to arbitrary complex spectra composed of multiple ripples and speech vowels, as illustrated in figure 29.11 (Shamma and Versnel, 1995; Kowalski, Depireux, and Shamma, 1996a,b). It should be emphasized, however, that A1 unit responses still exhibit nonlinear response characteristics such as half-wave rectification, saturation, adaptation, and often non-

monotonic rate-level functions. The effects of these nonlinearities on the STRF measurements are only partially understood and accounted for by these analysis methods (Kowalski, Depireux, and Shamma, 1996a,b).

Perceptual significance of the cortical multiscale representations

What is the perceptual significance of these multiscale representations, and what advantages do they provide to the processing of auditory and other sensory systems? From a scientific and engineering point of view, these representations are valuable since they provide explicit features that are perceptually significant. By understanding the properties of these features, we may be able to account for the stability and noise-robustness of our auditory percepts and facilitate the manipulation of these percepts in various engineering systems. We already discussed the perceptual correlates of noise-suppression in the early auditory stages. Here we elaborate on the perceptual correlates of the segregation of pitch and timbre cues in the cortical representation.

The hypothetical cortical representation of a complex speech segment is described in some detail in figure 29.6. As is evident in these panels, information about the pitch is preserved mostly in the finest spectral scales [panels B,C(2,4)] where the spectral harmonics are resolved. The lower and intermediate scales mostly represent the overall spectral envelope (a correlate of the timbre percept). The segregation of these cues may in turn explain the relative independence of these two percepts, e.g., producing different pitches with a particular instrument or playing the same note (pitch) on different instruments. This is an extremely useful property of the cortical representations in sound processing and recognition systems because it is often the case that one of the percepts is unnecessary. For example, to recognize a word or a phoneme (e.g., a vowel), the voice pitch is largely irrelevant. The opposite is true in recognizing a melody. Similarly, the segregation is useful in applications where a voice (pitch) or a phoneme (timbre) is morphed from one into another. Similar arguments can be advanced for the different temporal scales. For example, fast time scales are associated with sound transients (e.g., plucked instruments and speech consonants), and slow time scales with sustained sounds (e.g., bowed and wind instruments and speech vowels). Once again, the segregation can prove useful in many applications as in morphing.

The multiscale representation offers advantages with respect to robustness against noise. This is because different types of sounds (speech, music, and environmental noise) occupy distinct regions in the cortical multiscale representation, and hence interfering sounds occupying

FIGURE 29.10 Measuring the STRF using the reverse correlation method. (A) The spectrogram of one of the “random” stimuli used in the experiments. The stimulus consists of 200 ripples ranging from 0.2 to 2 cycles/octave, 4 to 40 Hz, and random starting phases. The results from many such stimuli are averaged at the end to compute the final STRF. (B) Period

histogram of responses to the stimulus in (A). Stimulus spectra that precede each spike are averaged to produce the STRF. (C) At the left is the STRF computed using the reverse-correlation method. The right panel shows the STRF of the same unit using the ripple analysis method.

different regions can be filtered out. For instance, speech sounds are largely concentrated in the intermediate scales (0.25–3 cycles/octave), lower frequency ranges (0.25–4 kHz) (Hillier, 1991), and with temporal modulations from 5 to 10 Hz (Wu et al., 1997). Consequently, outputs outside of these ranges can be removed to enhance the signal-to-noise ratio prior to further processing. In the best performing speech recognition systems to date, modulations in the speech spectrogram are bandpassed around 10 Hz to eliminate slowly varying background hums or to minimize the effects of rapid and irregular transients (Wu et al., 1997).

Finally, it is also possible to perform a variety of experiments with the multiscale representation in which different scales are eliminated in order to estimate their overall

contribution to the intelligibility of the signal. Another interesting manipulation is the translation of the activity pattern along the three different axes of the multiscale representation: the tonotopic (log-frequency), scale, and phase axes. Translations along these axes considerably alter the sound percept, but they do not seem to affect its intelligibility. For example, shifting the response patterns up and down the tonotopic axis by more than an octave produces speech that is easily comprehensible despite the large changes in the absolute frequencies of the spectral formants. This may be due to the fact that simple translations do not alter the overall shape of the corresponding cortical pattern. Similarly, translations along the scale, phase, and temporal axes produce changes in percept, but not in intelligibility. An interesting aspect of these

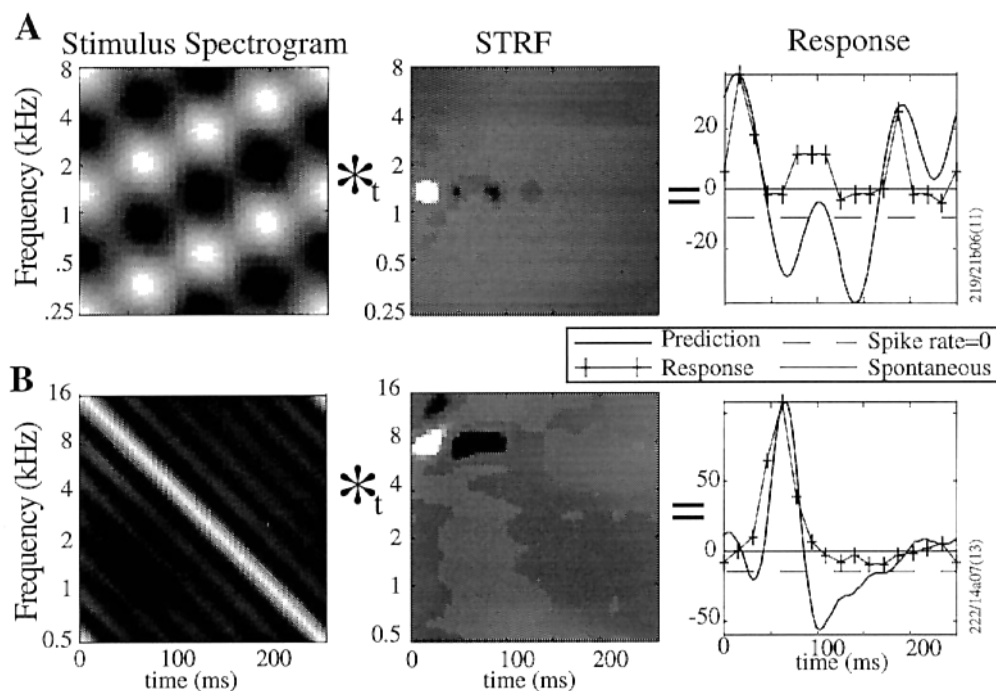

FIGURE 29.11 Predictions of responses to complex dynamic spectra using the STRF. (A) The predicted response is computed by convolving (along the temporal dimension) the STRF and the spectrogram. The stimulus shown is composed of two ripples (0.4 cycles/octave at 12 and -4 Hz). The predicted

waveform is shown juxtaposed upon the actual response (crosses) over one period of the stimulus. (B) Same as in (A) except for a stimulus consisting of ripples at (0.2 cycles/octave at 4 Hz + 0.4 cycles/octave at 8 Hz + . . . + 1.2 cycles/octave at 24 Hz, all in cosine phase).

(harmless) translations is that they are naturally produced by variations in the length of the vocal tract, its overall conical shape, or the rate of articulatory motion (speaking rate). Such variations are common across different speakers; consequently, our ability to normalize (and ignore) them may be partly explained by the invariance of our cortical representations to them.

We can identify many other features of the cortical representations whose perceptual correlates remain unexplored. For instance, the direction and rate of motion along the frequency axis are explicitly available. In figure 29.6, for example, B(1) and B(2) display fast, upward-moving energy as opposed to the slow, downward-moving energy of C(1) and C(2). Such information may be extremely useful in tracking and grouping variations common to one sound source, an essential preliminary step to segregating polyphonic signals and organizing a complex auditory scene.

Clearly, to appreciate all of the arguments presented here, we must be able to invert the cortical representation back to the acoustic signal so we can hear it. Procedures to accomplish this inversion are now available using convex-projection methods (Yang, Wang, and Shamma, 1992). The challenging aspects of this inversion are largely due to the several nonlinearities in the early stages of the auditory pathway. From a theoretical point

of view, success in inverting the cortical representation back to the acoustic stimulus illustrates the minimal loss of information through the many complex transformations along the auditory pathway (Yang, Wang, and Shamma, 1992). A convenient MATLAB-based package to perform and display the results of the auditory transformations and manipulations, and to invert the representations back to the acoustic stimulus is available upon request on <ftp://zikr.isr.umd.edu/speech/nsltools.tar.gz>.

30 Cortical Representations of Auditory Space

JOHN C. MIDDLEBROOKS

ABSTRACT The results of cortical lesions indicate that normal auditory cortical function is necessary for the perception of the location of a sound source. In the midbrain, neuronal maps of auditory space are well known. It is surprising, then, that efforts in several laboratories have failed to demonstrate a conventional topographical representation of sound-source location in the auditory cortex. An alternative view is presented here, in which single neurons are regarded as panoramic localizers. Experimentally, artificial neural networks were used to recognize single-unit spike patterns and, thereby, to identify the locations of sound sources. Spike patterns were shown to carry location-related information not only in their magnitudes but also in the timing of individual spikes. The representation of any particular sound-source location appears to be distributed across large populations of neurons.

Location in space is a conspicuous attribute of a sound source. Animals localize sound sources to track prey or to avoid becoming prey. Listeners exploit location-related information to aid in segregating a sound signal from a noisy background. Confronted with the cacophony of voices in a noisy office or in a cocktail party, humans can focus attention along a specific direction to single out a particular voice. In a typical listening situation, one has a sense of multiple discrete sound sources at well-defined locations.

In the visual and somatosensory systems, stimulus localization is a fairly straightforward matter. The locations of stimuli are mapped directly on the sensory epithelia, either the retina or the skin. Neurons in visual or somatosensory cortex have restricted receptive fields that, in essence, are determined by the area of the sensory epithelium that supplies their input. The locations of visual or somatic receptive fields vary systematically as a function of the locations of neurons in the cortex. Points in visual or somatic space map onto points in the cortex. In the auditory system, localization is much less direct. The auditory sensory epithelium contains a map of stimulus frequency, and consequently, auditory cortical topography is devoted to frequency representation. The locations of sound sources must be computed from

acoustical cues provided by the interaction of the incident sound wave with the head and external ears (see review by Middlebrooks and Green, 1991). The principal acoustical cues for the horizontal locations of sound sources are interaural timing differences and interaural level differences. The vertical and front/back locations of sounds are cued by characteristics of sound spectra that are introduced by direction-dependent resonances of the convoluted external ear.

Computation of sound-source locations takes place within structures of the auditory brain stem. Likely brain stem structures for detection of localization cues include the superior olivary complex for interaural difference cues and the dorsal cochlear nucleus for spectral cues. One product of the brain stem location computation is, in the midbrain superior colliculus, a map of auditory space. The auditory map lies in register with maps of visual, somatic, and motor space, and auditory units show restricted spatial receptive fields (see King and Schnupp, chapter 31 of this volume, for review of brain stem mechanisms and superior colliculus maps).

Auditory cortical function is essential for normal sound localization. Human patients that sustain lesions of the temporal lobe show deficits in localization of sounds presented on the side contralateral to the lesion (Greene, 1929; Wortis and Pfeiffer, 1948; Sanchez-Longo and Forster, 1958; Klingon and Bontecou, 1966). In cats, experimental lesions of the auditory cortex have little effect on reflexive head movements toward unexpected sounds (Thompson and Masterton, 1978); such movements probably are mediated by the superior colliculus. Auditory cortical lesions in cats do, however, block purposive behavior that requires sound localization. That is, after experimental unilateral lesions of the auditory cortex, cats are unable to walk to the source of a contralateral noise burst (Jenkins and Masterton, 1982). A unilateral localization deficit is perhaps the most conspicuous sign of a unilateral auditory cortical lesion.

Given that an intact auditory cortex is necessary for normal sound localization and that the brain is capable of constructing an auditory space map (at least in the superior colliculus), a rather obvious hypothesis would be

JOHN C. MIDDLEBROOKS Kresge Hearing Research Institute, University of Michigan, Ann Arbor, Mich.

that the auditory cortex contains a point-to-point map of auditory space. Such a map has been actively sought by several groups of investigators. Surprisingly, the consensus of those groups has been that there is no map, at least not in the form represented by the visual and somatic maps in the cortex or by the auditory space map in the superior colliculus. In this chapter, we begin by reviewing the characteristics of spatial tuning in the auditory cortex, citing some limited evidence for spatial topography. Nevertheless, we argue against the presence of a map of space in the auditory cortex. Then we present an alternative view of auditory spatial coding, in which individual neurons code locations throughout space and information about a particular point in space is distributed among a large population of neurons. Finally, we identify some of the features of neuronal spike patterns that carry auditory location-related information.

Spatial tuning of neuronal spike counts

Spatial coding in the auditory cortex has been studied most systematically in the cat, so this review focuses on that species. Spatial receptive fields have been described in cortical area A1 (Middlebrooks and Pettigrew, 1981; Brugge et al., 1994). Profiles of spike counts versus azimuth have been measured in area A1 (Imig, Irons, and Samson, 1990; Rajan, Aitkin, and Irvine, 1990a); area A2 (Middlebrooks et al., 1994, 1998), the anterior ectosylvian area (area AES: Korte and Rauschecker, 1993; Middlebrooks et al., 1994, 1998); and, to a limited degree, the anterior auditory area (area AAF: Korte and Rauschecker, 1993). The elevation sensitivity of spike counts has been measured in areas A2 and AES (Xu, Furukawa, and Middlebrooks, 1998). One might have predicted that area A1 or AES is specialized for sound localization. In the case of A1, that prediction comes from the observation by Jenkins and Merzenich (1984) that lesions restricted to area A1 impaired cats' localization of sounds presented contralateral to the lesion. In the case of area AES, Meredith and Clemo (1989) found that area AES is the only auditory cortical field that sends strong anatomical projections to the superior colliculus, which contains an auditory space map. Nevertheless, among the cortical areas in which spatial coding has been studied physiologically, no area stands out as obviously containing more spatially selective units or a more consistent spatial topography. Figure 30.1 shows some examples of azimuth and elevation sensitivity for units in area A2. The illustrated examples roughly span the range of sharpness of tuning that we have observed in that area.

The spatial sensitivity of units varies among units and, to a lesser degree, among cortical areas; but one

can make some generalizations. First, *spike counts are modulated by the location of a sound source*. Between 39% and 94% of units in areas AES and A2 showed more than 50% modulation of their spike counts by the location in azimuth of a noise burst (Middlebrooks et al., 1998); the exact percentages of units varied with cortical area and with sound level. In area A1, Rajan and colleagues (1990a) reported that 82% of units showed more than 50% modulation of their spike counts, and Imig and colleagues (1990) reported that 66% of units showed more than 75% modulation. Second, *the spatial tuning of units tends to be broad*. One can represent the spatial tuning of a unit by its *maximal receptive field*, which is the region within which a sound source could activate the unit above its resting level. In area A1, 75–85% of units showed maximal receptive fields that either filled a hemifield on one side of the cat or spanned all tested locations (Middlebrooks and Pettigrew, 1981; Brugge et al., 1994). Alternatively, one can represent the spatial tuning of a unit by its *best area* (Knudsen, 1982), which is the region within which stimuli activated the unit to more than 50% of its maximum spike count. Best areas spanned more than 180° for 58–85% of units in area AES and 81–97% of units in area A2 (Middlebrooks et al., 1998); again, the exact percentage of units varied with sound level. In area A1, best areas have been measured only in front of the cat, but so-called omnidirectional and hemifield units accounted for 82% of units (Rajan et al., 1990a). Third, *spatial receptive fields tend to expand in width with increases in stimulus sound level*. At stimulus levels near a unit's threshold, spatial receptive fields tended to be limited to a restricted region near the axis of greatest sensitivity of the external ear, most often the contralateral ear (Middlebrooks and Pettigrew, 1981; Brugge, Reale, and Hind, 1996). As sound levels were increased, receptive fields broadened at least until sound levels at the ipsilateral ear were high enough to activate inhibitory mechanisms. Brugge and colleagues (1996) reported that as sound levels were increased, the receptive fields of some ("unbounded") units in area A1 expanded until they occupied all tested locations, whereas the receptive fields of other ("bounded") units expanded only until they reached a boundary near the vertical midline. In areas AES and A2, the best areas of 88% and 77% of units, respectively, broadened as sound levels were increased from 20 to 40 dB above unit thresholds. The examples in figure 30.1 show spatial tuning that broadened with increasing sound level. Fourth, *the spatial preferences of units can change with changes in sound level*. For units that show sharp enough spatial tuning, one can define a "best-azimuth centroid," which is the spike-count-weighted center of a peak in a unit's azimuth profile, i.e., the azimuth

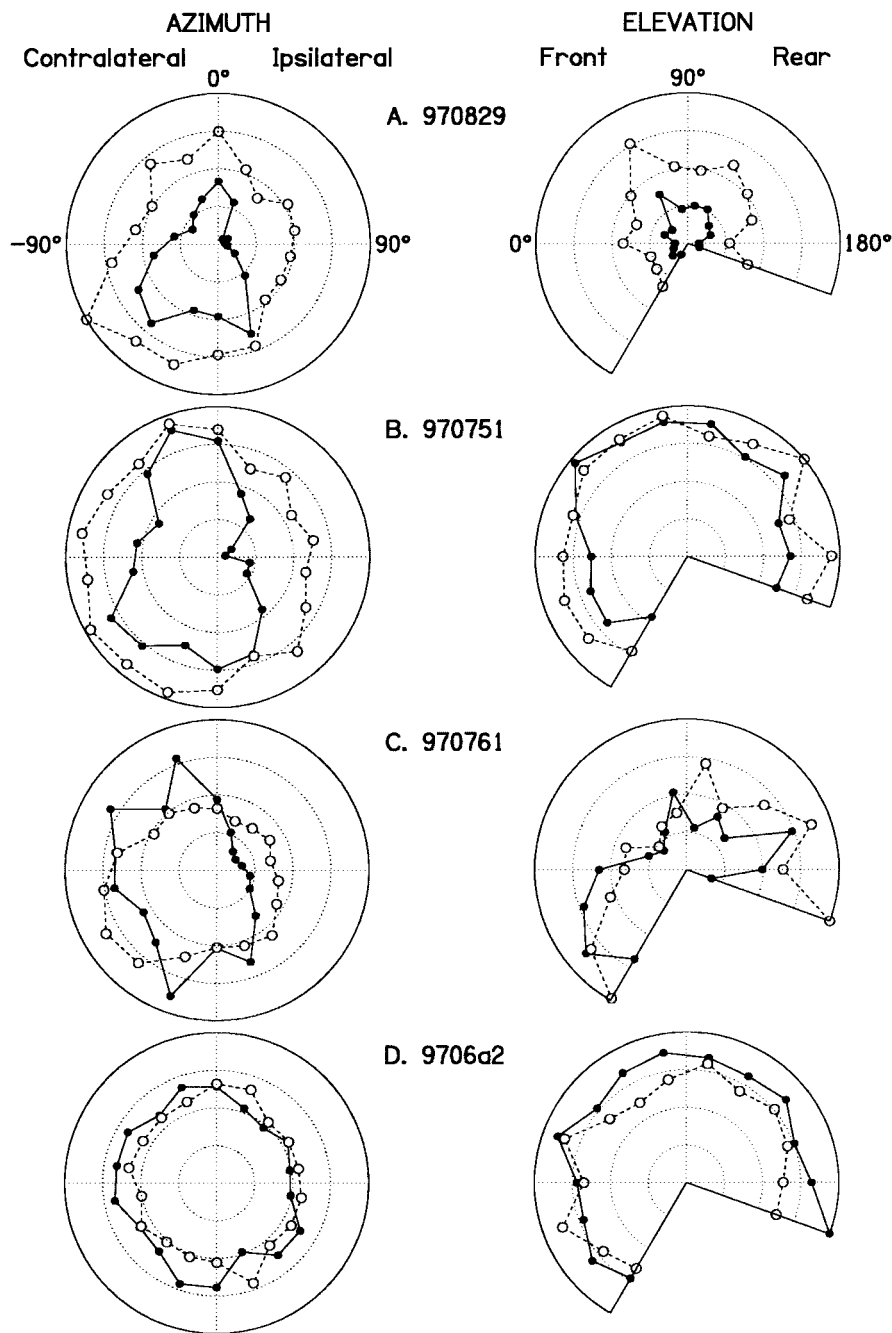

FIGURE 30.1 Spatial tuning of spike counts. Each row represents the azimuth tuning (left) and elevation tuning (right) of one unit recorded in area A2. In these polar plots, the angular dimension shows the sound-source location and the radial dimension shows the spike count averaged across 40 trials and

normalized to 100%. The azimuth plots are drawn as if looking down on the cat, and the elevation plots are views from the cat's left side. Filled and open symbols indicate measurements made with sound levels 20 dB and 40 dB, respectively, above units' thresholds.

to which the unit is "tuned" (Middlebrooks et al., 1998). In area AES and A2, more than half of the units that had measurable best-azimuth centroids when stimulus levels were 20 dB above threshold showed substantial changes in their centroids when sound levels were increased by 20 dB. Either the centroid shifted in location

by more than 40° or the unit became so broadly tuned that the centroid could no longer be measured. The units represented in figure 30.1B and C are examples that showed such changes in tuning. Similarly, one can see changes in azimuth tuning in illustrated data from area A1. Finally, *spatial profiles of units can show multiple*

peaks. The spike-count-versus-azimuth profiles of some units show two or more discrete peaks separated by well-defined valleys. The units represented in figure 30.1A and B are examples. Middlebrooks and colleagues (1998) found that 24% of units in area AES and 15% of units in area A2 had two or more best-azimuth centroids. In many instances, two best-azimuth centroids of a unit would lie in mirror symmetry with respect to the interaural axis, but that was not always the case. One also can see multiple peaks in illustrated data from area A1 (e.g., Imig, Irons, and Samson, 1990, figure 7).

It is a common observation in visual, somatosensory, and motor cortices that receptive fields are substantially larger than behavioral spatial resolution. Several models have addressed this issue under the general topic of “coarse coding” (e.g., Hinton, McClelland, and Rumelhart, 1986). In models of the motor cortex, Georgopolis, Kettner, and Schwartz (1988) have proposed a population code in which each neuron, although broadly tuned, represents a particular movement vector. Specific movements are represented by spike-rate-weighted vector sums of large populations of neurons. We have tried, with little success, to adapt such models to our data from areas AES and A2. The main problems are that the spatial preferences of units tend to change with increases in sound level, that units can show more than one preferred direction, and that many units show such broad spatial tuning that it is impossible to define a preferred direction.

Figure 30.2 shows, as a function of sound-source azimuth, the percentage of units recorded in areas AES and A2 that were activated to more than 25, 50, or 75% of their maximum firing levels. The plots suggest that a sound source at a level 40 dB above threshold located nearly anywhere on the side contralateral to the recording site would activate nearly all units to at least half of their maximal rates. Similarly, sounds at most contralateral locations would activate about 70% of units to more than 75% of their maximum rates. That is, a model that relied on spike counts to code locations in contralateral space would require that nearly all units discriminate locations with counts restricted to the maximum half of their dynamic ranges (i.e., spike counts could range between 50 and 100% of maximum). Indeed, the majority of units would need to operate in the upper quarter of their dynamic ranges (75 to 100% of maximum).

A topographical model of spatial coding in the cortex would require that the spatial preferences of units vary systematically as a function of the locations of units in the cortex. In support of a topographical model, the studies described above found that units that are located close together in the cortex generally tend to show similar spatial sensitivity. For instance, Middlebrooks and

FIGURE 30.2 Percentage of unit population activated by sound sources at various azimuths. These plots are derived from normalized spike-count data from 169 units recorded in area AES (top) or 62 units recorded in area A2 (bottom). The three lines in each panel show the percentages of the units that were activated above 25, 50, or 75% of each unit's maximum spike count by a noise burst that was 40 dB above each unit's threshold. Data are plotted as a function of sound-source azimuth. (Modified from Middlebrooks et al., 1998.)

Pettigrew (1981) found clusters of units that showed the same receptive field class. Units within a particular receptive field class, however, often occupied multiple clusters that were separated by units within a different receptive field class. Subsequent studies have confirmed the tendency of units with similar spatial tuning to aggregate in the cortex (Rajan et al., 1990b; Clarey, Barone, and Imig, 1994). Some studies have demonstrated examples of sequences of units along as much as 1.5 mm of electrode tracks across the cortex that showed system-

atic changes in spatial preferences (Imig, Irons, and Samson, 1990; Middlebrooks et al., 1998). Such sequences of units, however, were interspersed among sequences of units that showed very different spatial sensitivity. Investigators who have searched for spatial topography in areas A1, A2, or AES have consistently concluded that the organization that they found was not consistent with an integrated cortical map of auditory space.

Spatial information carried by neuronal spike patterns

In a conventional view of spatial coding, one assumes that activity in a single neuron is dedicated to coding a particular location in space. In that view, the broad spatial tuning of most auditory cortical neurons is a liability. Viewed another way, however, broad tuning might be an asset. The raster plot in figure 30.3 shows the spike patterns of a single unit elicited by sound sources at various locations. Throughout 360° of azimuth, the patterns varied in the number of spikes and in the timing within each burst of spikes. To the degree that various spike patterns of a unit are characteristic of specific locations, the activity of a unit might carry information about

many sound-source locations. That is, single units might code location *panoramically*. We have tested that hypothesis by attempting to identify sound-source locations by recognizing spike patterns of single units (Middlebrooks et al., 1994, 1998).

To test location coding by single units, we recorded multiple responses to sounds at each of a number of locations, then formed a *training set* from the responses in odd-numbered trials and a *test set* from the responses in even-numbered trials. The training set was used to train a computer algorithm to recognize the spike patterns associated with particular sound-source locations, and the test set was used to test the accuracy of such recognition. The isolation of training and test sets provided a form of cross validation of pattern recognition. Spike patterns from single trials proved to be too sparse to provide adequate recognition, often containing only one or two spikes. For that reason we formed multiple bootstrap averages of ensembles of eight trials. Bootstrap averages, formed by drawing multiple samples with replacement from a limited sample of responses, served to estimate the variance within an unlimited population (Efron and Tibshirani, 1991). We tested a variety of computer pattern-recognition algorithms and obtained satisfying results with several. The results presented here were obtained with a two-layer feedforward perceptron, which is a type of artificial neural network (Rumelhart, Hinton, and Williams, 1986). The inputs to the network were spike density functions quantized in fifty 1-ms bins, and the output was a scalar estimate of sound-source azimuth (details of the network architecture are given in Middlebrooks et al., 1998). We used bootstrap-average responses from the training set to train the network, then we presented responses from the test set to the trained network and measured the accuracy with which the network estimated sound-source azimuth.

Figure 30.4 shows the performance of an artificial neural network in estimating sound-source azimuth based on the responses of the unit represented in figure 30.3. Each plus sign represents the network output in response to one bootstrap-average spike pattern. The solid line shows the mean of the estimates at each source location. The dashed line with positive slope represents the loci of perfect estimates and the two dashed lines with negative slope represent loci of perfect front/back confusions (i.e., estimates that were mirror-symmetric to the source location with respect to the interaural axis). The mean-direction line tracks the perfect-performance line throughout most of the 360° of azimuth. The mean-direction line makes an abrupt jump across source locations 0° and ipsilateral 20°. That is the range of azimuths at which this and many other units showed the greatest change in spike counts. The network output discriminated left

FIGURE 30.3 Responses of unit 930157. This raster plot shows the responses of a unit to 100-ms noise bursts presented at various azimuths. Each dot represents one spike from the unit. Each row of dots represents the spike pattern in response to one stimulus presentation. Stimulus azimuths were varied randomly, but in this plot responses are sorted according to stimulus azimuth as indicated on the vertical axis. Eight trials at each azimuth are represented. The filled bar at the bottom represents the duration of the stimulus. (Modified from Middlebrooks et al., 1998.)

FIGURE 30.4 Network performance for unit 930157. Each plus sign represents the network output in response to input of one bootstrapped pattern. The abscissa represents the actual stimulus azimuth and the ordinate represents the network estimate of azimuth. The solid line connects the mean directions of network estimates for each actual stimulus location. The dashed line with positive slope represents perfect performance, and the two dotted lines with negative slope represent front/back symmetry between stimulus location and network output. (Modified from Middlebrooks et al., 1998.)

from right nearly perfectly except for source locations around the midline, and front/back confusions were fairly infrequent. Contrary to the conventional view that a single neuron is dedicated to coding a single point in space, the responses of this unit distinguished a broad range of locations.

We summarized the localization performance of neural networks by computing the median value of the magnitudes of errors across all trials at all locations. The median error computed in that way is sensitive to both the mean and the dispersion of the network estimates of location. Figure 30.5 shows the distribution of median errors for the units that we studied in areas AES and A2; data are from the condition in which sound levels were fixed at 40 dB above units' thresholds. All of the units in our sample produced median errors smaller than the value of 90° that is predicted given chance performance.

FIGURE 30.5 Distributions of median errors. These histograms show the percentages of the units in each sample that produced network performances with particular ranges of median errors. Top and bottom: Areas AES and A2, respectively. Left and right: 20 and 40 dB, respectively, above units' thresholds. (Modified from Middlebrooks et al., 1998.)

The median errors varied widely, with mean values of 43.7° for area AES and 43.5° for area A2. The distributions were unimodal, so we had no justification for segregating particular classes of units that were more or less location-sensitive. Nevertheless, one might imagine that the units with relatively small median errors have a greater role in location coding than those with larger median errors.

As noted, the spatial tuning of spike counts often changed with changes in stimulus level so, of course, changes in level normally resulted in changes in spike patterns. For that reason, a network that was trained

FIGURE 30.6 Mean directions of network output at five sound levels. An artificial neural network was trained with the responses of unit 950975 to noise bursts that roved in level from 20 to 40 dB above threshold in 5-dB steps. A test set contained responses from the same unit to stimuli at those same levels. Each line style indicates the mean direction of network output in recognition of responses in the test set to sounds of a single level. The steep slopes of the lines near -180° and 0° reflect the sharp changes in spike patterns across the rear and front midlines.

with responses to stimuli at one level tended to perform poorly in recognition of responses to stimuli at another level. Nevertheless, when networks were trained with responses to stimuli that roved across multiple levels, they were reasonably successful in recognizing responses to stimuli at any level within the trained range. Figure 30.6 shows the performance of a network that was trained with responses that roved in 5-dB steps between 20 and 40 dB above a unit's threshold. Here, network estimates are represented only by mean-direction lines. Each line represents classification of responses to a single sound level. Even though the same set of network weights was used to test all levels, the network was able to generalize across responses to all five sound levels. Note the sharp discrimination of locations across the front and rear midlines (i.e., near 0° and -180°). Apparently, the training procedure identified level-invariant features of spike patterns that carried azimuth-related information.

We favor the interpretation that the neurons we studied were adapted to code sound-source location. An alternative interpretation, however, is that the neurons

were sensitive only to a particular acoustical cue, such as interaural level difference, that happened to covary with azimuth. We tested the latter hypothesis by measuring the sensitivity of cortical units to the elevation of sound sources in the vertical midline. In the vertical midline, interaural difference cues are negligible and the principal cue for location presumably is the elevation-dependent transformation of spectral shape by one or both external ears. We recorded the responses of units to sound sources at various elevations, then performed a neural-network analysis analogous to our analysis of azimuth coding. Figure 30.7 shows the median errors of units in azimuth and elevation; the dashed lines indicate the means of the samples in each dimension. There was a weak but significant correlation between localization performance in azimuth and elevation. Generally, the units that coded azimuth well also coded elevation well. This suggests that single units can combine information from interaural difference cues and from spectral shape cues. It supports the interpretation that at least some of these neurons are adapted to code sound-source location.

Information-bearing features of neuronal spike patterns

The majority of studies of sensory coding by neurons tend to represent the responses of neurons only by the magnitudes of responses, i.e., either by the spike rate or by a count of spikes within a particular interval. We wished to test whether the magnitudes of responses captured all of the location-related information in spike patterns, or whether the timing of spikes might carry additional information. As an empirical test, we configured artificial neural networks to estimate sound-source azimuth by recognizing spike counts alone. We compared localization performance based on recognition of spike counts with that based on recognition of complete spike patterns, which contained both response magnitude and response timing. Figure 30.8 shows that comparison for units in area AES (top) and area A2 (bottom). On average, median errors were significantly greater when the neural network analyzed only spike counts than when the network analyzed complete spike patterns. A few of the points in the plots lie near the lines that indicates equal performance of spike counts and spike patterns. The bulk of the distributions, however, lay well above the line, in some cases showing median errors for spike-count recognition that were twice as large as the errors for spike-pattern recognition.

We have begun to explore specific features of spike timing that might carry location-related information

FIGURE 30.7 Correlation between network performance in azimuth and elevation. Each dot in the scatterplots represents, for one unit, the median error of the network performance in elevation versus that in azimuth. The upper and lower rows of panels show data from areas AES and A2, respectively. The

left and right columns of panels show data measured with stimuli 20 and 40 dB, respectively, above unit thresholds. The distribution of points in each panel showed a significant positive correlation. (From Xu et al., 1998.)

(Middlebrooks and Xu, 1996). In addition to spike counts, we have had some success with the *mean spike latency*, i.e., the mean of the latencies of all spikes within a spike pattern. Computation of mean latency was possible only because nearly all of the spike patterns that we observed consisted of a discrete burst of spikes, typically 10 to 50 ms in duration, at the onset of the stimulus (see figure 30.3 for an example). The mean latency is influenced by the first-spike latency and by the duration of each spike pattern. Figure 30.9 shows profiles of spike counts and mean latencies of one unit as a function of

sound-source azimuth. Across many azimuths, the spike count clearly was modulated by source locations, and mean latencies were rather constant. In other ranges of azimuth, indicated by the solid bars, sound sources produced spike counts that were relatively constant but mean latencies that were modulated by source location. This example shows but one way in which spike timing could provide location-related information that supplements information carried by spike counts.

We have used an analysis-of-variance procedure to compute the percentage of the variance in spike patterns

FIGURE 30.8 Accuracy of azimuth coding by spike counts and by complete spike patterns. This plot shows the accuracy of artificial-neural-network estimation of sound-source azimuth based on full spike patterns and spike counts. Full patterns (abscissa) consisted of spike density functions expressed with 1-ms resolution. Spike counts (ordinate) were the total number of spikes in each density function—i.e., the area under the density function. Top and bottom: Areas AES and A2. (From Middlebrooks et al., 1998.)

accounted for by spike counts, by mean latencies, and by some other measures of spike timing. For most of our sample, the spike count was the single term that accounted for the most variance, averaging nearly 40% of the variance. The variance in spike patterns accounted for by mean latencies was substantial, however, averaging around 25% across all units. In a few instances, mean latencies were closely correlated with spike counts, so mean latencies provided no information additional to

FIGURE 30.9 Azimuth profiles from mean spike count and mean latency. Data are from unit 930149 in area AES. Spike counts were averaged across all trials at each sound-source azimuth. Mean latencies were computed only for trials in which one or more spikes were recorded. Error bars are + or - standard error of the mean.

that available from spike counts. More often, however, the correlations between spike counts and mean latencies were very low, so the two terms were essentially independent.

We tested the capacity of spike latencies to provide independent location-related information. We configured neural networks either with spike counts as the only input or with two inputs consisting of spike counts and a mean-latency term. Addition of the mean-latency term substantially improved localization performance of the network. Localization based on two inputs was nearly as accurate as localization based on recognition of full spike patterns. We speculate that the difference in localization performance that remained between the two-input and the full-pattern networks was due to information that was carried by details of the timing of spikes within bursts that were not captured by the mean latency.

Throughout the preceding analysis, the timing of spikes was expressed in the form of latencies relative to

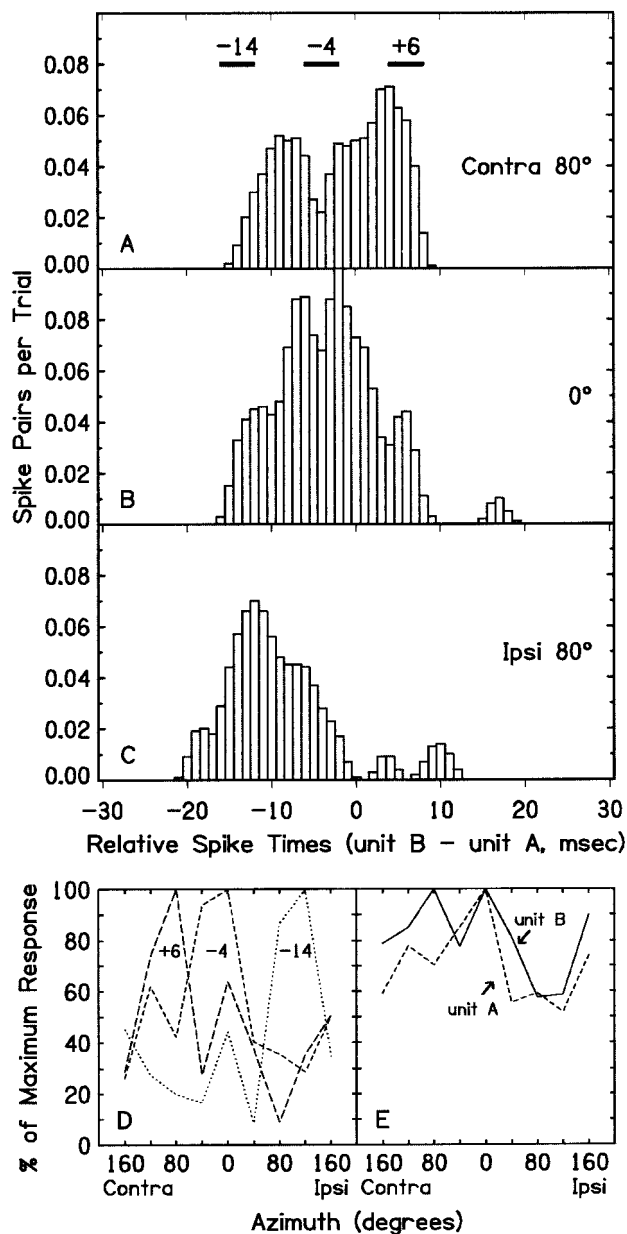

FIGURE 30.10 Relative spike times between two units. (A, B, C) Each bar represents the frequency of occurrence of a particular relative spike time measured between units A and B. Sound-source locations were contralateral 80° (A), 0° (B), and ipsilateral 80° (C) relative to the side of the recording site. The line segments numbered -14, -4, and +6 represent 4-ms relative-time windows centered at the indicated times. (D) Each line style shows, as a function of sound-source azimuth, the probability of recording a pair of spikes with relative times falling within a 4-ms window centered at the specified time. The profiles are normalized to 100%. (E) Different line styles show normalized spike counts versus sound-source azimuth for units A and B individually. (Modified from Middlebrooks, 1998.)

the onset of the stimulus. The onset time was known with microsecond precision to the investigator, but latency information would be of little use to an animal

without an independent signal to mark the sound onset time. We have begun to explore an alternative, that information might be coded by the *relative* timing among spikes in multiple units. We used a silicon-substrate probe (Wise, Angell, and Starr, 1970) to record simultaneously from units at multiple cortical sites. Figure 30.10 shows an analysis of one pair of units. Panels A, B, and C show the distribution of spike times in one unit (“unit B”) expressed relative to the times of spikes in another unit (“unit A”). The distributions shifted along the relative-time axis as the sound source location was varied among contralateral 80°, 0° and ipsilateral 80°.

One could imagine that a downstream neuron, or a behaving animal, might respond differently to spike pairs falling at different relative times, and such differential responses have been demonstrated (e.g., Segundo et al., 1963). We modeled an interneuronal comparator by counting the number of spike pairs that fell within restricted relative-time windows as a function of sound-source azimuth. Figure 30.10D plots the result of that computation for three 4-ms time windows centered at relative times of +6, -4, and -14 ms; those time windows are represented by line segments at the top of figure 30.10A. The probability of spike pairs at particular relative times was in this example substantially more azimuth-sensitive than were the spike counts of units A and B, taken individually (as shown in figure 30.10E). This simple analysis hints of a way to begin thinking about stimulus coding by the coordinated activity among populations of neurons.

Conclusions

Area A1 of the auditory cortex contains a well-known example of a topographic representation, known as “tonotopic organization,” in which low-to-high sound frequencies are represented by the caudal-to-rostral position of maximally activated neurons (Merzenich, Knight, and Roth, 1975). In that representation, processing of sounds of a particular frequency appears to be assigned to a restricted region of cortex. In contrast, the representation of sound-source location in any of the auditory cortical areas that have been explored appears not to be topographic. Single units are broadly tuned for source location, their tuning changes with changes in stimulus level, and the progression of preferred locations across the cortical surface is at best fragmented. The results that we have obtained favor a different, *distributed*, organization in which the responses of single neurons code locations across a broad range, and accurate sound localization is derived from information that is distributed among neurons throughout a cortical field.

This distributed organization contrasts with the precise retinotopic organization with which we are familiar in the primary visual cortex. Yet, as one moves higher in the extrastriate visual cortical hierarchy, the precision of retinotopy successively deteriorates. It would be surprising if the object of higher-level cortical processing were to degrade spatial precision. It seems more likely that, at higher levels of the visual hierarchy, visual space is coded in some form that does not require a precise point-to-point cortical topography. In the primary auditory pathway, there is no spatial topography imposed by the organization of the auditory periphery, so it is perhaps not surprising that space coding takes a nontopographical form.

The notion that stimulus-related information might be coded by the timing of neuronal spikes is well established in auditory nerve and auditory brainstem research. Coding by spike timing in the auditory cortex is more novel. In the visual system, information-theoretic analyses have demonstrated that some three to five dimensions of spike patterns, including magnitude and timing dimensions, can carry stimulus-related information (e.g., Richmond and Optican, 1987). The issue of information coding by temporal details of spike patterns is, however, a matter of some controversy in the visual literature (Shadlen and Newsome, 1994; Softky, 1995). In our work in the auditory cortex, raster plots of spike patterns show conspicuous stimulus dependence, and errors in decoding of sound-source locations can double when temporal features of spike patterns are discarded. The stimulus dependence of cortical spike timing presumably is a product of neural transmission delays and membrane time constants, and one might guess that similar mechanisms are available for decoding of information stored in spike times.

If we speculate about mechanisms by which biological neural networks might decode spike patterns, we move perilously close to a model that demands neurons that are sharply tuned for sound-source locations. Such neurons have been sought throughout much of the auditory cortex largely without success. An alternative view, which we favor, is that there is no overt decoding of spike patterns by single neurons and that, instead, the decoded information exists only in the behavior or perception of the whole animal. In ongoing experiments we are exploring the principles by which the magnitude and timing of spike patterns might act to synchronize specific subpopulations of neurons, thereby selecting those subpopulations to contribute to behavioral output.

ACKNOWLEDGMENTS I am pleased to acknowledge the contributions of my colleagues Drs. Ann Clock Eddins, David M. Green, Li Xu, and Shigeto Furukawa in collecting and analyzing

data and in helping to develop many of the ideas presented here. Ms. Zekiye Onsan provided expert technical assistance. I am grateful for research funding from the NIDCD.

31 Sensory Convergence in Neural Function and Development

ANDREW J. KING AND JAN W. H. SCHNUPP

ABSTRACT Perhaps one of the biggest challenges for sensory networks is to permit convergence of information from different processing channels that is both functionally and developmentally appropriate. Neurons in the superior colliculus receive converging inputs from different sensory modalities. This allows excitatory and inhibitory interactions to take place, which process the spatiotemporal relationship between diverse sensory signals. These interactions occur within the framework of topographically aligned sensory maps, which appear to mediate rapid, goal-directed behavior in a multisensory environment. Visual and somatosensory maps arise from spatially ordered projections from their receptor surfaces. In contrast, the synthesis of a computational map of auditory space requires that neurons become tuned to matching values of monaural and binaural localization cues that are initially encoded in separate brainstem pathways. Merging auditory and visual representations in the superior colliculus during development is an activity-dependent process, in which visual signals, possibly arising from the superficial layers of this nucleus, are used to adjust auditory spatial tuning.

Coding of sensory information within and across modalities

A fundamental question in sensory physiology is the manner in which behaviorally significant information is encoded and processed by neurons in the brain (Ferster and Spruston, 1995; Rieke et al., 1997). For single neurons, the parameters of sensory signals can be specified by variations in the frequency at which nerve impulses are generated (rate coding) and by the precise timing of those impulses (temporal coding). Within populations of neurons that differ in their sensitivities, stimulus parameters are represented by spatiotemporal patterns of activity, and, in many areas of the brain, the tuning of neighboring neurons varies systematically to form sensory maps (place coding). Recent work has focused on synchronization of discharges among different groups of neurons as an additional and potentially highly versatile way of signaling sensory events. Identifying whether the brain actually uses these strategies as a means of encoding sensory information is very difficult. Nevertheless,

valuable insights have been obtained from modeling studies and by relating behavioral performance to normal or experimentally induced abnormal patterns of neural activity (Laurent, 1997; Middlebrooks, chapter 30, this volume; Rieke et al., 1997). What does seem certain is that the relative contribution of different coding schemes varies both within and across different sensory systems.

Sensory maps are ubiquitous in the brain and offer several advantages for analyzing information. For example, lateral interactions between neighboring neurons tuned to adjacent positions in stimulus space can compute contrast or generate sensitivity to stimulus motion. Although mapping is certainly not essential for extracting new features in the environment, this arrangement does provide an efficient use of neural connections.

Perhaps the best examples of neural maps that can be related to stimulus coding are so-called computational representations (Knudsen, du Lac, and Esterly, 1987) that are isomorphic with some aspect of the outside world, but which are not directly related to the anatomical arrangement of axons leaving the receptor cells. Among these are maps of auditory space in the midbrain of barn owls (Knudsen, du Lac, and Esterly, 1987; Konishi, 1995) and mammals (King and Carlile, 1995), which are brought into register in the superior colliculus (SC) with projectional maps of visual space and of the body surface (figure 31.1). As a consequence, the different sensory signals from a single object in space converge on common motor output pathways and evoke shifts in gaze toward the location of that target. The alignment of visual, auditory, and somatosensory maps also provides a means by which different sensory modalities can interact to determine the responses of SC neurons. As the distributed representations of the posterior parietal cortex illustrate (Andersen et al., 1997), interfacing sensory and motor processing need not necessarily take place within a topographically organized framework. But in the SC, a nucleus concerned primarily with reflex orienting movements, the presence of congruent sensory and motor maps appears to optimize the neural

FIGURE 31.1 Representation of sensory space in the SC. The inset shows a sketch of the SC in the ferret midbrain. The superficial layers are exclusively visual, whereas the deeper layers receive multimodal inputs. Stimulus azimuth is mapped onto the rostrocaudal axis (white arrow), and elevation onto

the mediolateral (black arrow) axis of the nucleus. The portion of visual and auditory space represented within the SC is indicated by the arrows to the right, and corresponds approximately to the extent of the visual field of the contralateral eye.

circuitry in ways that are computationally efficient and hence amenable to experimental investigation.

Implications of multisensory convergence at the neuronal level

One of the most interesting properties of multisensory neurons, both in the SC and elsewhere in the brain, is that their responses can be modulated according to the spatiotemporal relationships between converging stimuli from different modalities. Compared to their responses to individual stimuli presented alone, these neurons may exhibit significantly enhanced firing when stimuli of different modality are delivered in close temporal and spatial proximity (reviewed by Stein and Meredith, 1993). This property, which is known as multisensory facilitation, is thought to increase the salience of events that may activate more than one sense organ, potentially making them easier to detect and localize.

The neural basis for multisensory integration is unknown. Enhancement and occlusion between converging signals could arise if signals are added linearly because the spike activity of neurons is typically a nonlinear function of their inputs. Figure 31.2 illustrates a sigmoidal input-output function in which the response evoked by the linear summation of auditory and visual input signals depends on the operating point along this

function, i.e., on the intensity of the stimuli. This simple mathematical model appears to provide a good approximation for the bimodal responses of SC neurons (figure 31.3; Schnupp et al., 1997). For example, the expansive nonlinearity in the rising phase of the sigmoid correctly predicts that the most pronounced enhancements occur for stimuli just above threshold. It has been suggested that the NMDA class of glutamate receptors might be responsible for enhanced bimodal responses (Binns and Salt, 1996; Stein and Meredith, 1993). However, the multisensory properties observed in the SC are perhaps more easily explained in terms of an essentially linear integration of converging inputs. Summation of inputs followed by nonlinear activation functions may also explain interactions between converging inputs in the visual cortex (Freeman and Ohzawa, 1990), posterior parietal cortex (Andersen et al., 1997) and motor cortex (Capaday, 1997).

Because multisensory facilitation in SC neurons is observed only when each stimulus falls within its excitatory receptive field, the alignment of those receptive fields would appear to be a necessary property if response enhancements are to signal multisensory cues associated with a common source (Stein and Meredith, 1993). Different sensory systems represent spatial information in different coordinates, with those of visual space centered on the retina and those of auditory space

FIGURE 31.2 Schematic illustrating how a neuron with a non-linear input-output function (sigmoid) might produce greatly facilitated responses ($R_{v+a} > R_v + R_a$) simply by summing input activations linearly ($A_{v+a} = A_v + A_a$). Note that the degree of facilitation depends on the magnitude of the inputs (stimulus intensity), which will determine the operating point along the nonlinear input-output function. For sigmoidal functions, maximum facilitation would be observed for inputs close to unit threshold.

on the ears and head. However, by incorporating signals that relate to the position of the sense organs, the sensory responses of SC neurons appear to be transformed into a single coordinate framework that is commonly referred to as motor-error (Sparks and Groh, 1995). Motor-error coordinates indicate the difference or error between current eye position and the location of the sensory target. This coordinate transformation is a necessary requirement if information from different modalities is to be combined in a meaningful manner and used to guide orientation movements to stimuli irrespective of their modality.

Construction of topographically aligned sensory maps in the superior colliculus

Neural maps of visual and auditory space are constructed in different ways. By acting like a camera, the eye forms a map of visual space on the retina. This map is preserved, albeit in a slightly distorted form, at different levels of the brain as a result of topographically organized projections. Spatially ordered projections also arise from the cochlea, but result in central maps of sound frequency, not source location. The first step in matching the inputs of different modalities in the SC is therefore the synthesis within the brain of a map of auditory space. This is achieved by tuning neurons to acoustic localization cues

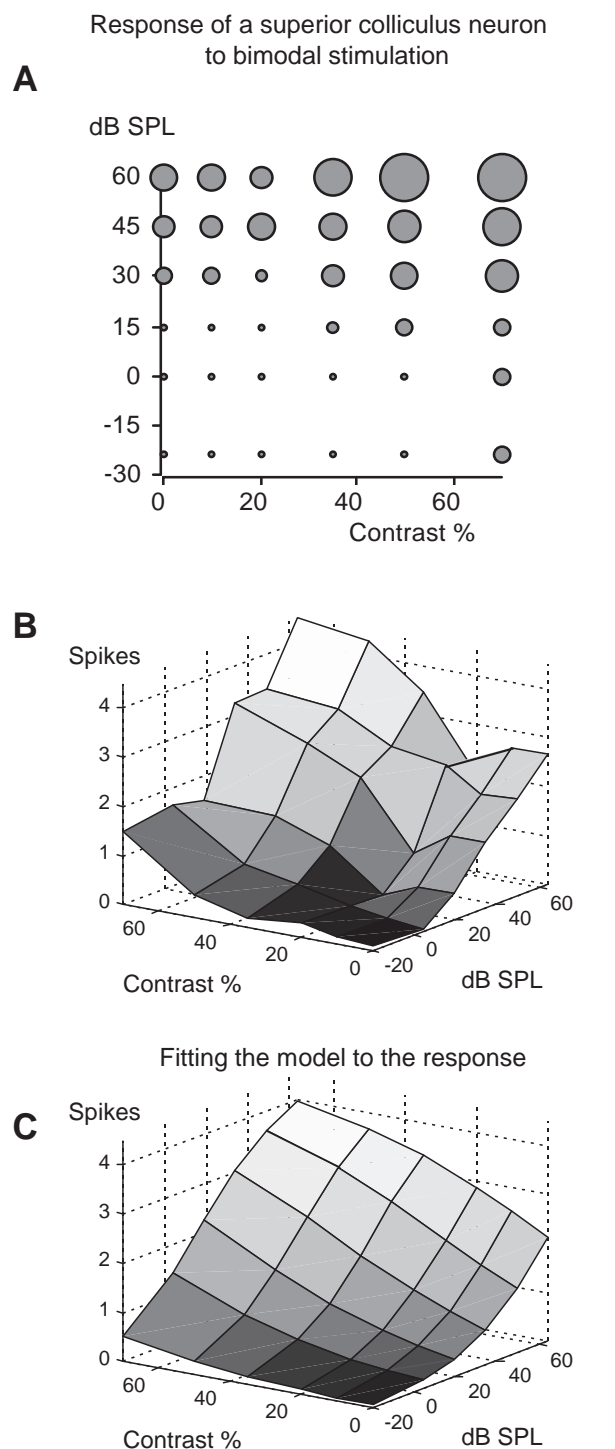

FIGURE 31.3 (A) Visual-auditory joint-sensitivity function of a bimodal unit in the deeper layers of the ferret SC, measured with simultaneously presented visual (sinusoidally modulated luminance) and auditory (broadband noise) stimuli. Each of the gray filled circles has a radius proportional to the spike count (per stimulus presentation) obtained at the contrast/sound pressure level combination indicated by the axes. (B) Same data as in A, shown as a 3D surface plot. (C) Predicted responses obtained by fitting a sigmoidal model (logistic equation) to the data shown in A and B.

that correspond to different directions in space (King and Carlile, 1995; Konishi, 1995; Middlebrooks and Green, 1991). These cues include interaural time differences (ITDs), which are determined by the distance between the ears, and interaural level differences (ILDs), which result from the directional filtering properties of the external ears plus the shadowing effect of the head. In addition, the direction-dependent changes in the sound spectrum imposed by the external ears can be used, under some circumstances, to localize sounds monaurally (King and Carlile, 1995; Middlebrooks and Green, 1991).

To a large extent, the initial processing of these auditory localization cues takes place within separate pathways of the brain stem. In mammals, auditory nerve fibers carry signals from the cochlea to the ventral (VCN) and dorsal cochlear nuclei (DCN). The processing of binaural localization cues begins in the superior olivary complex, which receives converging inputs from each VCN. As a result of their synaptic and biophysical specializations, some VCN cells transmit temporal information with great fidelity to the medial superior olive (MSO), where sensitivity to ITDs of the order of tens of microseconds emerges (Oertel, 1997). Neurons in the lateral superior olive (LSO) receive a direct excitatory projection from the ipsilateral VCN and an indirect inhibitory projection from the contralateral side. Consequently, they are sensitive to ILDs. MSO and LSO neurons then relay ITD and ILD information, respectively, to the midbrain. The pathways that process monaural spectral cues are still largely unexplored. However, both physiological (Young et al., 1992) and behavioral (May, 1998) studies suggest an involvement of the DCN, which projects directly to the midbrain.

The spatial selectivity of neurons in the mammalian SC appears to be based on ILDs and monaural spectral localization cues (King and Carlile, 1995). The synthesis of a map of auditory space therefore involves the correct merging of spatial information from different brainstem circuits. As part of this process, inputs are also combined across different frequency channels to produce the broad and often complex spectral tuning of SC neurons. Only recently has evidence been obtained to indicate whether in mammals the representation of auditory space first emerges at the level of the SC or is relayed there from other auditory areas.

The mammalian SC is innervated by several auditory areas in the brain stem and cortex (e.g., Edwards et al., 1979; King, Jiang, and Moore, 1998; Meredith and Clemo, 1989). In most species, the largest inputs arise from the ipsilateral inferior colliculus, particularly the nucleus of the brachium (BIN) and the external nucleus (ICX) of that structure. The projection from the ipsilat-

eral BIN to the SC is spatially organized, with rostral and caudal regions of the BIN projecting primarily to corresponding regions of the SC (King, Jiang, and Moore, 1998; figure 31.4). At sound levels high enough to stimulate both ears, a topographic representation of sound azimuth is found along this axis in both nuclei (Schnupp and King, 1997; figure 31.5A,C). In addition to this place code or map of auditory space, some neurons show variations in spike latency and temporal discharge pattern with sound source location. This would suggest

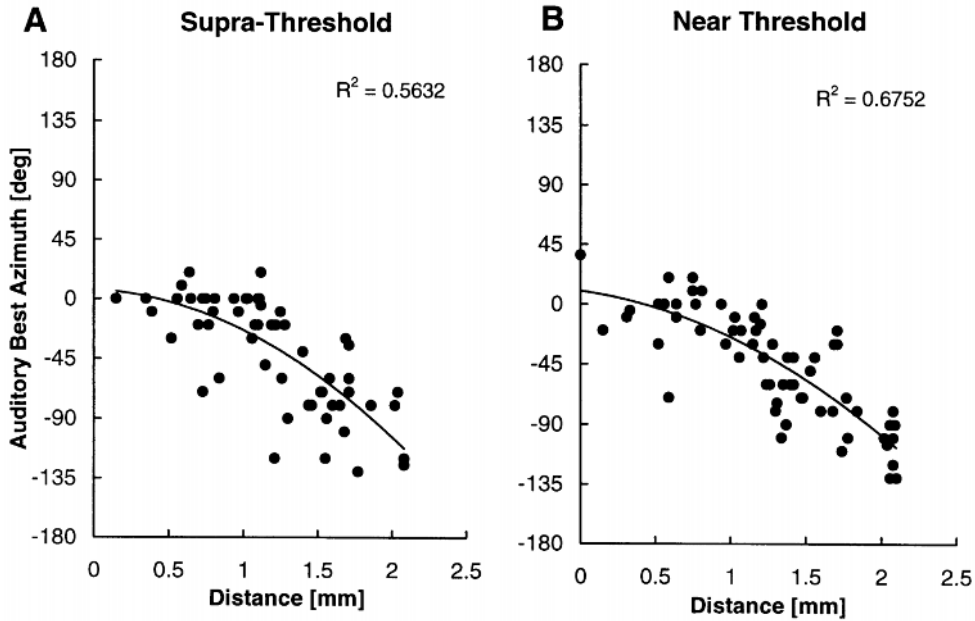

FIGURE 31.4 Distribution of retrograde labeling in subcortical auditory structures after injections of green fluorescent microspheres into rostral SC and red microspheres into caudal SC. The frontal sections are arranged from rostral (top) to caudal (bottom). The open and filled areas in the SC indicate the injection sites of green and red tracers, respectively. The small open and filled circles show the positions of retrogradely green or red labeled cells, respectively. The small asterisks indicate doubly labeled cells. The pattern of labeling indicates that the projection to the SC from the nucleus of the brachium of the inferior colliculus may be spatially ordered along the rostro-caudal axis. More limited labeling is also found in the contralateral auditory midbrain and in other auditory brainstem nuclei. BIC = brachium of the inferior colliculus, MGB = medial geniculate body, ICX = external nucleus of the inferior colliculus, ICC = central nucleus of the inferior colliculus, PAG = periaqueductal gray. (Data from King, Jiang, and Moore, 1998.)

Superior Colliculus

Brachium of the Inferior Colliculus

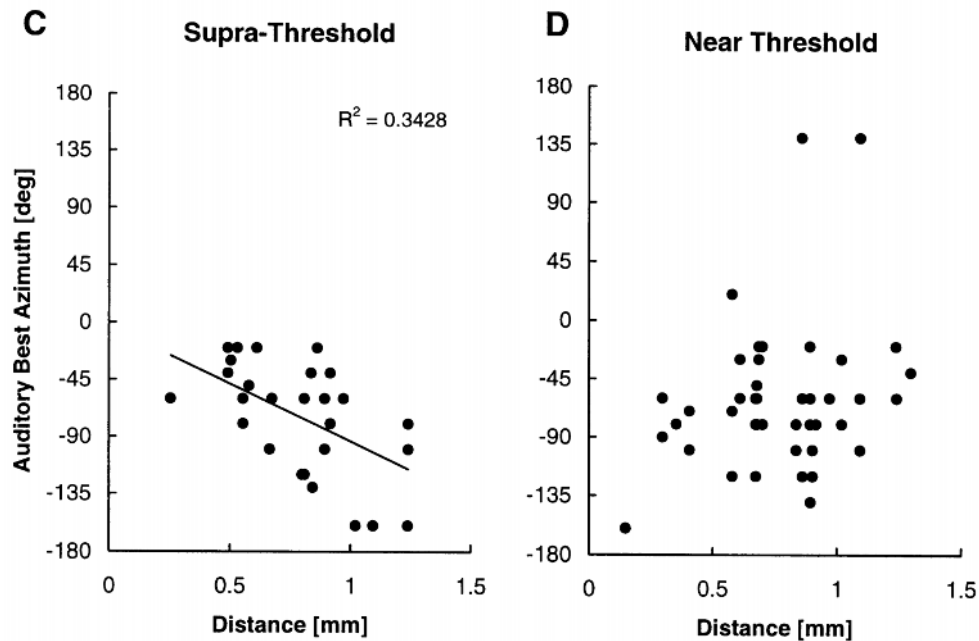

FIGURE 31.5 Topographic representation of sound source azimuth in the SC (A,B) and in the BIN (C,D). The suprathreshold data were obtained at 25–30 dB and the near threshold data at 10–15 dB above unit threshold. The topography in the SC is best described by a second-order polynomial, and does

not change with sound level. In the BIN, however, a systematic relationship between best sound azimuth and recording site is apparent only at suprathreshold sound levels. (From Schnupp and King, 1997, with permission.)

that, as in the auditory cortex (Middlebrooks, chapter 30, this volume), multiple forms of stimulus coding may operate simultaneously in the midbrain (Schnupp and King, 1997).

In comparison to the SC, auditory neurons in the BIN are less sharply tuned for sound direction, exhibit a greater incidence of ambiguous tuning to two or more sound directions and, in terms of the distribution

FIGURE 31.6 Convergence of inputs to the SC may sharpen auditory spatial tuning. Distribution of 50% spatial bandwidths (azimuth profile widths in degrees at 50% of maximum response) for single unit (gray area) and “bicellular” (black and white bars) response profiles in the BIN. Bicellular response profiles were obtained by counting only those spikes that occurred within 5 ms of a spike fired by another unit recorded simultaneously with the same electrode. For unit pairs whose

firing was significantly correlated (black bars), the bicellular response profiles were significantly more sharply tuned than their parent single-unit response profiles. Possible effects of short-term interactions between single units can be disrupted by “shuffling” the data from repeated presentations of the stimulus. The resulting azimuth profiles (white bars) still show a significant improvement in spatial tuning compared to the single-unit profiles.

of best azimuths, a less precise map of auditory space. Furthermore, although the spatial selectivity of SC neurons remains topographically organized over a range of sound levels (figure 31.5A,B), near-threshold best azimuths do not vary systematically with recording site in the BIN, but are instead clustered around the interaural axis in the contralateral hemifield (figure 31.5D). Sound elevation is also mapped within the SC (King and Carlile, 1993; King, Moore, and Hutchings, 1994), but not apparently in the BIN (Schnupp and King, 1997).

Monaural spectral cues appear to be largely responsible for the azimuth and elevation topography observed in the SC at near threshold sound levels, which is unaffected by occlusion of or cochlear ablation in the ipsilateral ear (King, Moore, and Hutchings, 1994; Palmer and King, 1985). Even at higher sound levels, where SC neurons exhibit a systematic variation in sensitivity to ILDs (Wise and Irvine, 1985), spectral cues are still required to resolve front/back confusions due to the spatially ambiguous nature of binaural cues at individual sound frequencies (Carlile and King, 1994). The lack of both elevation topography and near-threshold azimuth topography, together with the greater incidence of spatially ambiguous response profiles, suggests that a full complement of spectral localization cues may not be en-

coded in the BIN. Presumably, afferents from the ICX, in which a topographic representation of sound azimuth has also been reported (Binns et al., 1992), or other auditory structures contribute additional information that is used in the construction of the two-dimensional map in the SC.

Cues to the importance of converging inputs in the generation of higher-level sensory response properties can be obtained by recording simultaneously from several neurons in the circuit. Recordings from pairs of units in the BIN reveal that azimuth response profiles constructed from spike pairs firing in near synchrony are more sharply tuned than those of the individual neurons of each pair and much more like those of SC neurons (figure 31.6). An improvement in spatial tuning is observed even if short-term correlations in neural activity are removed in the analysis by shuffling the responses to repeated stimulus presentations. This would indicate that active synchronization between neurons is not required, and that simple convergence from different BIN neurons with similar, overlapping response properties could contribute to the more precise representation in the SC. Furthermore, the presence in several auditory brainstem nuclei, including the ICX, of GABAergic neurons that project to the SC (Appell and Behan, 1990), suggests

that inhibitory inputs also contribute to shaping the spatial response properties of SC neurons. Given the importance of sensory experience, both auditory and visual, in the development of the auditory space map in the SC (King and Carlile, 1995), it seems likely that activity-dependent mechanisms are involved in selecting the most appropriate combinations of inputs from the BIN and other auditory structures during early life.

Aligning visual and auditory maps during development

The developmental emergence of sensory representations in the brain reflects the maturation of the peripheral sense organs as well as that of the afferent connections and synaptic properties that underlie stimulus processing. Although the projection from the BIN is spatially organized on the day of birth in ferrets (Jiang, King, and Thompson, 1995), the topographic order in the representation of auditory space in the SC matures gradually during the second and third postnatal months (King and Carlile, 1995). Postnatal sharpening of the auditory receptive fields of SC neurons has also been observed both in guinea pigs (Withington-Wray, Binns, and Keating, 1990a) and in cats (Wallace and Stein, 1997). This is likely to be due in part to the maturation of auditory localization cues, which change with the size and shape of the head and ears (King and Carlile, 1995). Nevertheless, the brain stem circuits that process ILDs also undergo maturational changes during normal postnatal development (Sanes, 1993). Moreover, it is now well established that experience-mediated plasticity in the developing auditory representation plays a critical role in establishing the congruence with the map of visual space in the SC (reviewed by King and Carlile, 1995; Knudsen and Brainard, 1995).

A role for vision in refining the development of auditory spatial tuning has emerged from studies in which visual spatial cues have been manipulated during early life. Disrupting the pattern of visual input by binocular eyelid suture in barn owls (Knudsen, Esterly, and du Lac, 1991), guinea pigs (Withington, 1992), and ferrets (King and Carlile, 1993) leads to the development of an auditory representation that tends to possess normal topographic order, but which is nevertheless degraded in various ways. If the visual map is displaced relative to the head by surgical deviation of the eye (King et al., 1988) or by prism rearing (Knudsen and Brainard, 1991), the auditory representation undergoes a corresponding shift so that the two modalities continue to share a common topographic organization.

A similar adaptive change in auditory spatial tuning can be induced by manipulation of the acoustic localization cues available to the developing animal. Occluding one ear will attenuate and change the phase of incoming sounds, thereby altering the ILD and ITD values that correspond to positions in visual space. A period of monaural occlusion in young owls will shift the tuning of neurons in the SC toward these new binaural cue values, particularly if normal visual cues are available (Knudsen and Mogdans, 1992). Removal of the external ear structures, the facial ruff and preaural flap, in this species is also followed by a compensatory change in neuronal tuning to ILDs and especially ITDs (Knudsen, Esterly, and Olsen, 1994). These changes are sufficient to reestablish at least a partial correspondence between the representation of the auditory localization cue values and the map of visual space.

The developing mammalian auditory system appears to possess a similar capacity to adjust to the altered binaural cues produced by occlusion of one ear. If a plug is introduced in infancy, a near normal representation of auditory space develops in the ferret SC (King and Carlile, 1995; King et al., 1988). Unlike in owls, however, disruption of spectral localization cues in infancy does not lead to a compensatory change in mammalian auditory spatial tuning (Schnupp, King, and Carlile, 1998). Even though normal visual cues are present, bilateral removal of the pinna and concha of the external ear in juvenile ferrets degrades the auditory representation in the SC and therefore its alignment with the unchanged visual map (figure 31.7A). Other parts of the auditory pathway are also likely to be affected by abnormal spectral localization cues and, behaviorally, these animals exhibit a similar impairment in their capacity to judge the location of broadband sound sources (Parsons et al., in press; figure 31.7B). Other experimental manipulations that have been carried out in both birds and mammals have revealed a role for sensory experience in aligning the visual and auditory representations in the SC that seems to be quite consistent across different species. The physiological and behavioral consequences of early pinna and concha removal in ferrets appear to indicate a greater dependence on spectral cues provided by the external ears for auditory localization in mammals than in barn owls.

It seems likely that the anatomical projections underlying the auditory map are first established in an experience-independent manner. Correlated visual and auditory activity then appears to be used to refine the auditory spatial tuning of SC neurons, so that map registration is achieved irrespective of individual differences in the size, shape, and relative position of the different

sense organs. In each species that has been examined, visual cues play a primary role in calibrating the preferred sound directions of SC auditory neurons. This guiding influence of vision only becomes apparent, however, if sufficient, reliable acoustical information is also available during development.

In recent years, attention has shifted to the neural mechanisms that match auditory and visual signals during development. One possibility is that this may involve a Hebbian mechanism in which auditory inputs are selectively weakened or stabilized according to whether they are active at the same time as visual inputs that converge on the same neuron. In particular, the biophysical properties of NMDA receptors suggest a possible basis for detecting concurrently active synaptic inputs (Fox and Daw, 1993). Much of the evidence implicating NMDA receptors in the development of sensory systems has come from studies showing that blockade of these receptors with appropriate antagonists can prevent the rearrangement of maps that would otherwise occur in response to experimentally manipulated inputs. If synaptic plasticity contributes to normal sensory maturation, and, in particular, to fine-tuning the registration of visual and auditory representations in the SC, it should be possible to disrupt this process through

the application of NMDA-receptor antagonists during an appropriate stage of development.

Various techniques are available for the application of drugs to discrete regions of the brain. For example, implants made from Elvax, a slow-release polymer, release agents for a period of up to several months (Schnupp et al., 1995; Smith, Cordery, and Thompson, 1995). Implantation of Elvax containing NMDA-receptor antagonists onto the dorsal surface of the SC in juvenile ferrets specifically interferes with the development of the auditory representation (Schnupp et al., 1995). Chronic application of these antagonists in adult animals does not change the topographic order of either the visual representation in the superficial layers (figure 31.8A) or the auditory representation in the deeper layers (figure 31.8B) of the SC. Consequently, the registration of the maps is unaffected. The visual map is also unaltered in ferrets reared with Elvax implants from before eye opening and the onset of hearing until after the age at which the auditory space map normally emerges (figure 31.8A), most probably because the retinocollicular projection is already mature at implantation (Chalupa and Snider, 1998; King et al., 1996). The auditory representation, in contrast, does not develop normally in these animals (figure 31.8B) and the registration with the unchanged visual map is disrupted. By themselves, these findings do not demonstrate that NMDA receptors subserve a role as coincidence detectors; blocking these receptors may simply reduce synaptic currents to levels below those required to induce plastic changes. Nevertheless, they do confirm the importance of neural activity in establishing the alignment of different sensory maps. As well as providing a possible trigger for the activity-dependent steps that lead to the emergence of a precise and unambiguous representation of auditory space, NMDA-receptor mediated currents appear to be particularly involved in expressing visually guided changes in auditory spatial tuning of midbrain neurons in prism-reared owls (Feldman, Brainard, and Knudsen, 1996).

Besides correlating auditory and visual inputs to the SC, NMDA receptors may play another role in the development of the auditory space map. At sound levels close to unit threshold, the auditory representation in all but the most rostral region of the mammalian SC appears to be derived from monaural pinna cues (King, Moore, and Hutchings, 1994; Palmer and King, 1985), whereas sensitivity to ILDs maintains the topographic order at higher levels (Wise and Irvine, 1985). As discussed above, monaural and binaural localization cues are likely to be processed initially by separate, parallel pathways within the auditory brain stem. The abnormal auditory responses observed following

FIGURE 31.7 Physiological and psychophysical consequences of disrupting spectral localization cues by removal of the pinna and concha of the external ear in juvenile ferrets. (A) In normal adult ferrets more than 75% of SC auditory units are tuned to single azimuthal positions, and most of the others exhibit broad, typically hemifield, response profiles (bottom panel, black bars). The best azimuths of the tuned units are closely aligned with those of visual units in the overlying superficial layers (top left panel). Recordings from adult ferrets in which the pinna and concha had been removed bilaterally in infancy revealed a marked increase in the proportion of auditory units with ambiguous spatial tuning (bottom panel, gray bars, “bilobed” and “complex” categories). This is expected, given that the external ears provide important information for resolving front/back ambiguities in binaural localization cues. These auditory units also exhibited much less topographic order and consequently a poorer alignment with the visual map (top right panel: the best azimuths of tuned units are shown as triangles and two best azimuths for each bilobed unit as filled and open circles). (B) Performance in an absolute localization task. Noise bursts were delivered from one of 12 speakers positioned around the animal. The animals had been trained to approach the active speaker for a water reward. Top panels: Mean (left) and standard deviation (right) of the error in localizing brief (40 ms) sounds for normal ferrets (black lines) and after early pinna and concha removal (gray lines). Bottom panel: Incidence of front/back errors at different stimulus durations. Overall, ferrets perform less well after early removal of the pinna and concha and make more front/back errors. (Single-unit data from Schnupp, King, and Carlile, 1998.)

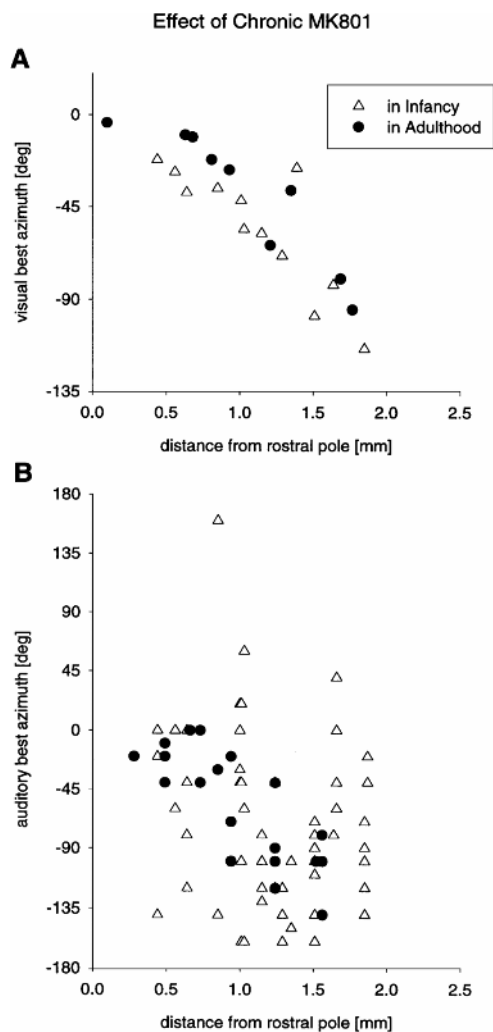

FIGURE 31.8 Effects of chronic NMDA-receptor blockade on the topographic organization of the representations of visual space in the superficial layers and of auditory space in the deeper layers of the ferret SC. (A) Multiunit visual best azimuths are plotted against the rostrocaudal position of the recording site within the SC. These data are from juvenile (61–70 days old, open triangles) and adult animals (filled circles) that, 5–6 weeks earlier, received Elvax implants containing the non-competitive NMDA antagonist MK801. A clear topographic order is apparent in both cases, which is not significantly different from that found in normal, age-matched ferrets. (B) The auditory best azimuths recorded in the animals that received Elvax implants in adulthood also show a normal topographic order (filled circles). However, those recorded in the animals treated with MK801 during the period over which the auditory space map normally matures (open triangles) show significantly more scatter than their age-matched controls. (Data from Schnupp et al., 1995.)

removal of the pinna and concha in juvenile ferrets suggest that spectral cues play a critical role in establishing the sensitivity of SC neurons to combinations of monaural and binaural cues that unambiguously identify sound source direction (Schnupp, King, and

Carlile, 1998). Appropriately combining different localization cues appears to be an activity-dependent process that may also conform to Hebbian rules of synaptic plasticity.

Where does visual calibration of auditory spatial tuning take place?

If visual signals do contribute to the sharpening and ordering of auditory spatial response profiles, it would seem necessary that inputs from the two modalities converge on the same neuron, so that any error between them can be measured. Because most neurons in the deeper layers of the mammalian SC and in the barn owl's optic tectum are responsive to stimuli in more than one modality, one might expect that the interactions would take place in those structures. However, prism-rearing experiments in owls have shown that altered visual cues also affect the ITD tuning of neurons in the ICX (Brainard and Knudsen, 1993), which provides auditory input to the tectum via a topographically organized projection (Knudsen and Knudsen, 1983). These changes, which take several weeks to develop, appear to be brought about by an anatomical reorganization of the projection to the ICX from the central nucleus of the inferior colliculus (Feldman and Knudsen, 1997). How visual signals feed into this circuit is not yet clear, nor is it known whether equivalent changes occur in the mammalian brain.

The representation of auditory space in the ICX of guinea pigs is unaltered by dark rearing (Binns, Withington, and Keating, 1995), a procedure that degrades the development of the map in the SC (Withington-Wray, Binns, and Keating, 1990b). However, the contribution of the ICX to the auditory representation in the SC in mammals is currently uncertain. On the other hand, some of the auditory neurons in the ferret's BIN are also visually responsive (Schnupp and King, 1997). This raises the possibility that, as in owls, the nucleus providing the principal, spatially ordered auditory input to the SC (figure 31.4) may also be influenced by visual experience.

In cats, multisensory neurons in the deeper layers of the SC first respond to visual stimuli more than a week after the first auditory responses appear. With increasing age, both auditory and visual receptive fields become progressively sharpened as the neurons begin to integrate information from different modalities (Wallace and Stein, 1997). Because of these factors, the visual map in the deeper layers would not appear to provide an ideal template for an activity-dependent refinement of auditory spatial selectivity. In contrast, in carnivores, the retinocollicular projection to the superfi-

cial layers exhibits a high degree of topographic order throughout development (Chalupa and Snider, 1998; King et al., 1996) and a mature visual map is already present in those layers by the time of natural eye opening (Kao et al., 1994; King and Carlile, 1995; King et al., 1996). Superficial-layer neurons are thought to play a role in visual processing, and their contribution to the sensorimotor function of the SC is uncertain (Casagrande et al., 1972; Edwards et al., 1979). Nevertheless, interlaminar connections between the superficial and deep layers of the SC have now been demonstrated in several species (e.g., Behan and Appell, 1992; Hall and Lee, 1997; Mooney, Huang, and Rhoades, 1992). These

may provide an anatomical substrate by which the relatively small and early developing visual receptive fields of superficial-layer neurons could contribute to the maturation of sensory responses in the deeper layers of the SC.

In ferrets, aspiration of the caudal part of the superficial layers on the day of birth has minimal effects on what is left of the visual map in the remaining rostral region or on the auditory spatial selectivity of neurons found beneath that region (King et al., 1996; King, Schnupp, and Thompson, 1998). Recordings made from the intact rostral part of the SC in adulthood show that both superficial-layer visual and deep-layer auditory neurons are

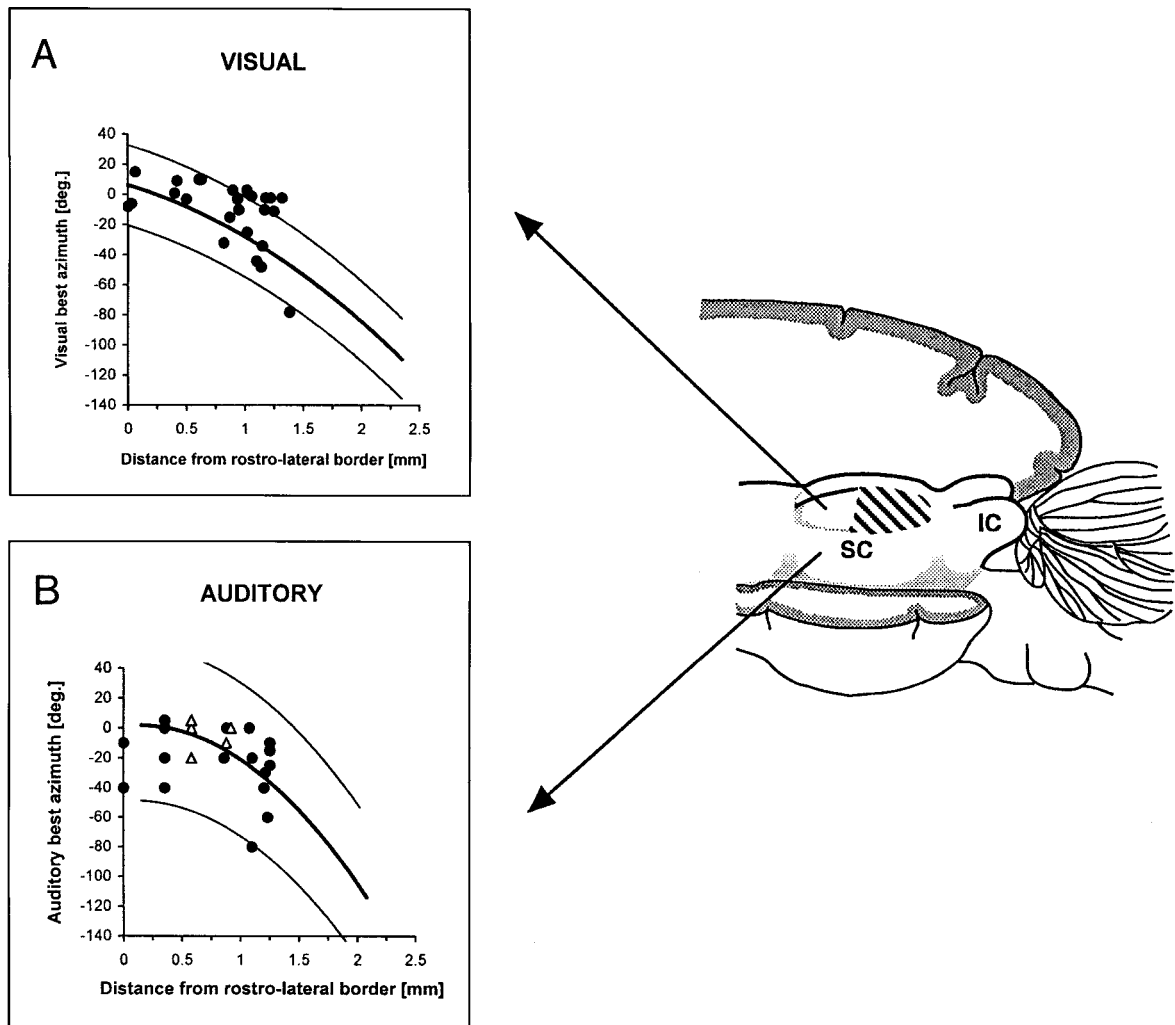

FIGURE 31.9 (A) Visual representation in the remaining superficial layers of the SC in adult ferrets following aspiration of the caudal portion of those layers on the day of birth. The azimuthal best positions are plotted against the distance of their recording sites along the rostrocaudal axis of the SC. (B) Auditory representation beneath the remaining portion of the superficial layers. The open triangles represent the auditory best azimuths of units that were also visually responsive, whereas

the filled circles indicate the values obtained from unimodal auditory neurons. The two lines in each panel represent two standard deviations on either side of the polynomial function that provides the best fit to the visual and auditory maps in normal ferrets. The hatched area of the SC in the parasagittal view on the right indicates the aspirated region of the superficial layers. (From King et al., 1996, with permission.)

FIGURE 31.10 Auditory representation in the deeper layers of the adult ferret SC from which the overlying superficial layers had been removed by aspiration on the day of birth; plotted as in figure 31.9B. The open triangles represent the auditory best azimuths of units that were also visually responsive, whereas the filled circles indicate the values obtained from unimodal auditory neurons. (From King et al., 1996, with permission.)

tuned to azimuthal angles that span a restricted part of anterior space, falling either within or very close to the normal range of values (figure 31.9). Although confined primarily to the contralateral hemifield, the preferred sound directions of units recorded ventral to the superficial-layer lesion exhibit significantly more scatter, with many values falling outside the normal range (figure 31.10). Many deep-layer neurons in this region of the SC still receive visual inputs, presumably originating from extrastriate cortical areas, but these are apparently insufficient to rescue the auditory spatial tuning of bimodal cells. These results identify a potential role for superficial-layer neurons in establishing the alignment of sensory maps in the SC. However, it remains to be seen whether and how visual activity in the superficial layers can fine-tune the developing auditory responses either in the SC or at an earlier stage in the pathway.

Conclusions

The SC has proved to be an extremely useful structure in which to examine the way in which spatial informa-

tion provided by a variety of sensory cues is synthesized and integrated. Where neurons in the SC and in multisensory areas of the cortex receive converging inputs from two or more modalities, they tend to have receptive fields that are roughly aligned in space. In terms of variations in firing rate, SC neurons are tuned to restricted regions of sensory space and it is the alignment of these preferred stimulus directions across different modalities that most clearly characterizes the registration of the maps.

Compared to visual and somatosensory representations, considerable central processing is involved in establishing a neural map of auditory space. Activity-dependent processes appear to play an essential role during development in matching the tuning of individual neurons to different auditory localization cues that correspond to specific positions in visual space. Subsequent transformation of sensory signals into a common coordinate frame, which most likely incorporates efference copy signals, can allow receptive field alignment to be maintained in the face of independent mobility of the sense organs. This enables different sensory cues to be substituted for one another and to be combined in ways that can improve the accuracy with which multimodal events are localized. Many perceptual experiences depend on cooperative interactions between multiple sensory inputs. For example, the improvement in speech perception that results from watching movements of the speaker's lips may involve a synthesis of linguistic visual cues and speech sounds in the auditory cortex (Calvert et al., 1997). It seems highly likely that the principles of sensory convergence and integration exhibited by SC neurons are also relevant to the processing of complex inputs elsewhere in the brain.

ACKNOWLEDGMENTS This work was supported by a Wellcome Senior Research Fellowship to Andrew King and by a Wellcome Prize Studentship and subsequently a Dunhill Research Fellowship (awarded by Defeating Deafness: The Hearing Research Trust) to Jan Schnupp. We are grateful to Roland Baddeley, Simon Carlile, Jim Giles, Ze Dong Jiang, Richard Lanyon, David Moore, Carl Parsons, Adam Smith, and Ian Thompson for their valuable contributions to some of the experiments described in this chapter, and to David Moore, Alan Palmer, and Dan Sanes for their comments on the manuscript.

32 The Song System: Neural Circuits Essential throughout Life for Vocal Behavior and Plasticity

ALLISON J. DOUPE, MICHAEL S. BRAINARD, AND NEAL A. HESSLER

ABSTRACT The learned vocal behavior of songbirds provides a useful model system for sensorimotor learning and behavior in general, and for the learning and production of human speech in particular. In young birds in the process of learning, song changes rapidly, and is dramatically sensitive to the removal of auditory feedback. In contrast, the adult song of many species was thought to be quite stable and independent of hearing. In zebra finches, however, it is now clear that stable adult song is actively maintained using auditory feedback, because deafening of these birds as adults causes their song to deteriorate slowly (Nordeen and Nordeen, 1992). Little was known, however, about whether the neural pathways involved in adult song modification and maintenance are similar to those important during learning. By analyzing the song behavior and neurophysiology of adult zebra finches, both in normal and deafened birds, we have found that the anterior forebrain pathway, a circuit crucial for initial song learning, is also essential for the changes in adult song that normally result from deafening, and is highly active during singing in adults. Moreover, singing-related activity in this pathway is strongly modulated by social context, which is known to affect both adult song and song learning. These findings on the regulation of vocal plasticity in the song system of adult birds shed light on the nature of signals for learning at all ages, as well as on developmental changes in the capacity for plasticity.

Birdsong is a complex vocal motor behavior with a number of parallels to human speech, particularly the fact that it is learned early in life with a strong dependence on hearing (Konishi, 1965; Marler, 1970). In adult birds of most species, however, song is highly stable, and was thought to be largely independent of auditory feedback (Konishi, 1965), perhaps being driven solely by a central pattern generator. Recently, however, it has become clear that, at least in zebra finches and related species, adult song requires continued auditory feedback for its stable maintenance: The songs of zebra finches deafened as adults deteriorate slowly over the

course of weeks to months, although with a great deal of variability between individuals in the speed and amount of deterioration (Nordeen and Nordeen, 1992). This dependence on auditory feedback—though much less dramatic than that seen in young birds, in whom song invariably degrades rapidly after deafening (Nottebohm, 1968; Price, 1979)—nonetheless indicates that sensory feedback functions in adult song. This is true of speech as well: Although humans show much more preservation of speech if they become deaf as adults rather than during childhood, the speech of deaf adults does gradually deteriorate, with a great deal of inter-individual variability (just as in songbirds), but sometimes to the point of unintelligibility (Cowie and Douglas-Cowie, 1992).

The new observations that hearing is essential for maintained vocal production in adult zebra finches raise the questions of how and where the signals from auditory feedback act in the brain. Songbirds, like humans, have a specialized neural circuit devoted to vocal learning and production, known as the song system, which is a likely location for many of the neural mechanisms involved in song. Studies of the adult song system may have advantages for uncovering how neural signals mediate the matching of vocal motor output to sensory feedback. For example, in adult birds, the intended outcome of learning, the adult song, is already known, while in juvenile birds learning for the first time, the ultimate target of learning is of necessity unclear until later. Moreover, in young birds the instructive signals and mechanisms for learning are inevitably entangled with the processes underlying the rapid growth and development of the song system, which occur at the same time as initial song learning. In adults these developmental processes are largely complete and should not confound the mechanisms involved in maintaining learned song. Finally, studying adult birds and comparing them to juveniles can address whether the mechanisms that subserve normal song maintenance parallel those required

ALLISON J. DOUPE, MICHAEL S. BRAINARD, and NEAL A. HESSLER Departments of Physiology and Psychiatry and Keck Center for Integrative Neuroscience, University of California, San Francisco, Calif.

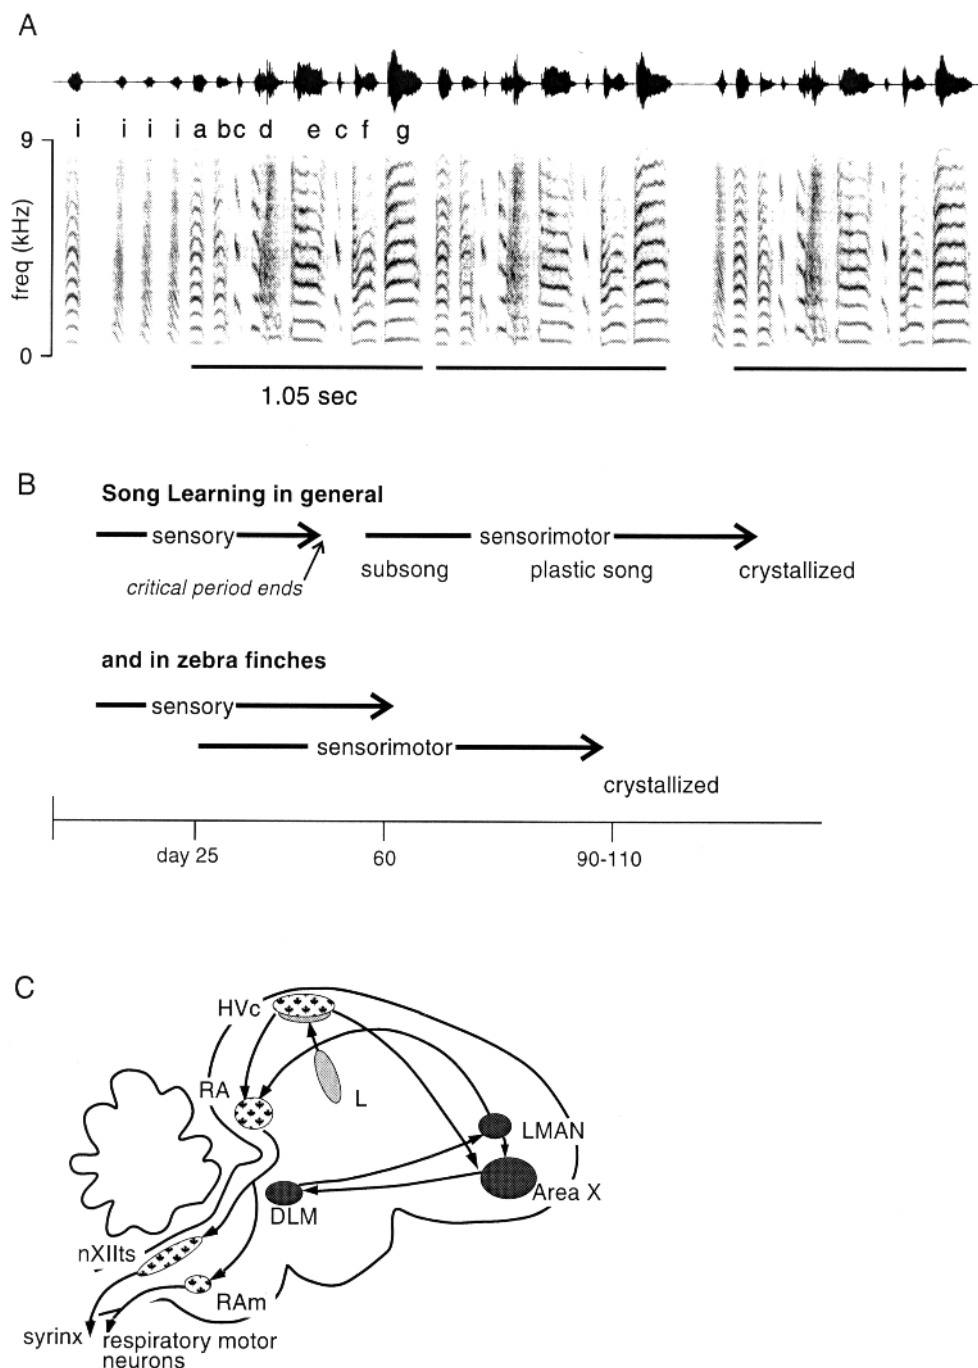

FIGURE 32.1 (A) Birdsong. A spectrogram (frequency vs. time plot, with amplitude indicated by the darkness of the signal) of a typical zebra finch song shows the characteristic features of song. The smallest elements, called “notes,” are either sung alone or combined to form “syllables” (marked with lowercase letters); particular stereotyped sequences of syllables, called “motifs” in zebra finches (indicated by dark bars), may be repeated one to many times, preceded by a variable number of short introductory notes (i). (B) Timeline of song learning. The general features of song learning are similar in all songbirds. The initial memorization or sensory learning of the song is followed by sensorimotor learning. During this vocal practice phase, the bird first produces the highly variable and

amorphous sounds of subsong, followed by plastic song, in which motor rehearsal of learned song is evident. Finally, the bird develops stable or crystallized song. The details of song learning vary from species to species. Seasonal species generally learn their song over the first year of life, while zebra finches, which mature rapidly (within 3 months), learn to sing during these 3 months and show extensive overlap between the two phases of learning. (C) The song system. Simplified schematic of the song system. Motor pathway nuclei are shown filled with a pattern, and the anterior forebrain (AF) nuclei are dark gray. The field L complex (light gray) provides the major source of auditory input to the song system, via its direct and indirect connections to HVc.

during learning, and whether and how vocal plasticity changes through the life cycle.

Birdsong learning: The behavior

As a prelude to investigating adult song maintenance, it is useful to define birdsong and review what is known about its learning. Birdsong, like speech, consists of ordered strings of sound called syllables, separated by brief silent intervals (figure 32.1A), and is learned by songbirds when they are young. The phenomenology of song learning is strikingly similar to human speech learning. Songbirds do not produce adult-like sounds when they first begin to vocalize, but instead sing rambling immature song akin to the babbling of human infants. Young birds then gradually refine their vocalizations until they sing mature adult song, which strongly resembles the songs of adults that they heard while growing up. Numerous behavioral studies have revealed that this learning occurs in two stages, both of which are critically dependent on hearing (figure 32.1B). In an initial “sensory learning” phase, young birds do not vocalize a great deal, but hear the song of an adult tutor or tutors (usually the male parent and neighboring males), committing much of this song to memory (Marler, 1970). This must occur within a time-limited critical period analogous to sensitive periods for human language learning. Later, during a period of vocal practice or “sensorimotor learning,” birds begin to sing, gradually matching their initially immature vocalizations to their memorized song or “template.” At the end of this phase, birds produce stereotyped, “crystallized” song, which in many species is stable for the rest of the bird’s life (for reviews, see Konishi, 1985; Kroodsma and Miller, 1996).

If deafened prior to sensorimotor learning so they cannot hear their own voices while learning to sing, songbirds never produce normal song (Konishi, 1965). Thus, birds cannot simply internally translate the memorized song into the correct pattern of vocal motor commands; rather, they must actively develop the required motor mapping by evaluating sensory feedback from their own vocalizations (figure 32.2A). Moreover, this dependence on auditory experience is developmentally regulated: Loss of hearing by adult songbirds whose song is stable has much smaller and slower effects on vocal production than the same loss during the active sensorimotor matching of initial song acquisition (Konishi, 1965; Nordeen and Nordeen, 1992; Price, 1979). This, too, is similar to humans, who are strongly dependent on hearing early in life for normal speech acquisition, but show much more preservation of speech if they become deaf as adults (Cowie and Douglas-Cowie, 1992).

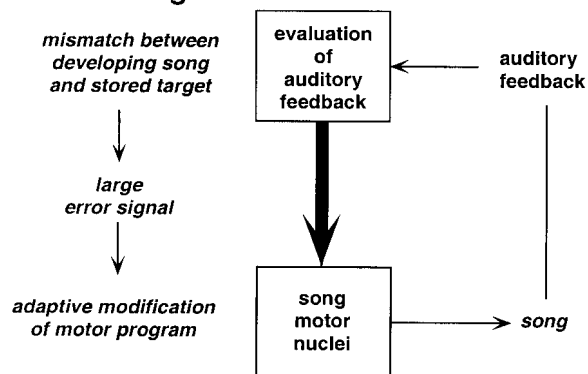

Brain structures specialized for song learning and production

Songbirds also resemble humans in having evolved a complex set of neural structures in the forebrain that are essential for song learning and production (figure 32.1C; Nottebohm, Stokes, and Leonard, 1976; Bottjer et al., 1989). The so-called song “motor” pathway controls the midbrain and brainstem areas that regulate the muscles of the vocal tract and of respiration, and is essential throughout life for normal singing. This includes the song motor control nucleus HVC, which projects to the premotor nucleus RA; RA then connects to midbrain vocal control areas, respiratory premotor neurons, and motor neurons for the musculature of the avian vocal organ, the syrinx (see Wild, 1997, for review). Lesions of HVC or RA at any age dramatically disrupt singing, sometimes resulting in complete muteness, akin to that seen in some human aphasias (Nottebohm, Stokes, and Leonard, 1976). This circuit is thus critically involved in song production throughout life.

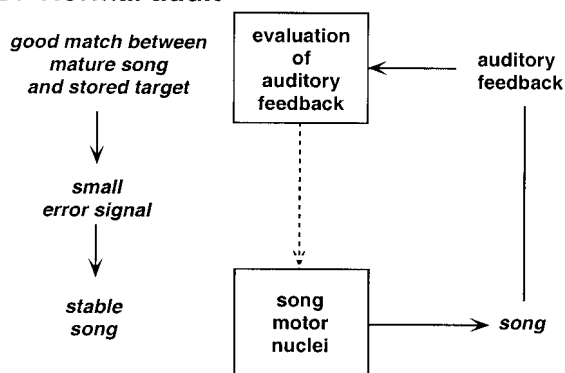

A second circuit of forebrain nuclei also links HVC to RA, but via an indirect loop through the basal ganglia and thalamus (Bottjer et al., 1989; Okuhata and Saito, 1987). This pathway through the anterior forebrain (AF) includes the striatal-like nucleus area X, the medial portion of a dorsolateral thalamic nucleus (DLM), and a forebrain nucleus perhaps analogous to prefrontal cortex, the lateral magnocellular nucleus of the anterior neostriatum (LMAN). The importance of this AF pathway changes developmentally in a manner similar to that seen for hearing. Lesions or pharmacological inactivation of its component nuclei markedly disrupt initial song learning and production. In contrast, lesions in adult birds singing crystallized song have no obvious effect on song production (Basham, Nordeen, and Nordeen, 1996; Bottjer, Miesner, and Arnold, 1984; Scharff and Nottebohm, 1991; Sohrabji, Nordeen, and Nordeen, 1990). Thus, the AF pathway has some critical function during learning.

Because both the AF circuit and auditory feedback are essential during learning, and less so in adulthood, one role of the AF may be to mediate the auditory feedback critical to normal song development (Doupe, 1993). Consistent with this hypothesis, AF nuclei contain auditory neurons that, in adult zebra finches, are highly song-selective (Doupe, 1997): They respond much more strongly to playback of the bird’s own song (BOS) than to songs of conspecifics (other individuals of the same species), and respond better to BOS than to temporally altered versions of this song (that is, played in reverse or with the syllables out of order). Neurons so specialized for song could play a role in the sensory evaluation of

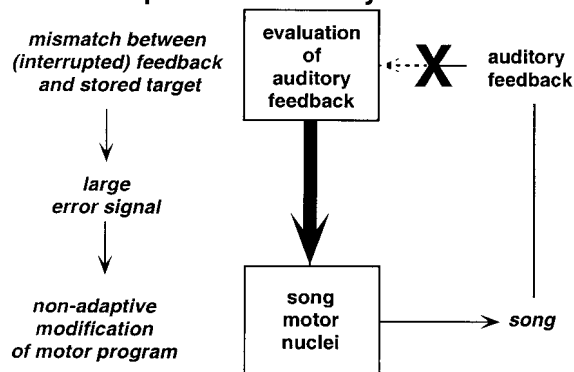

A. Learning

B. Normal adult

C. Interruption of auditory feedback

D. Interruption of error signal & feedback

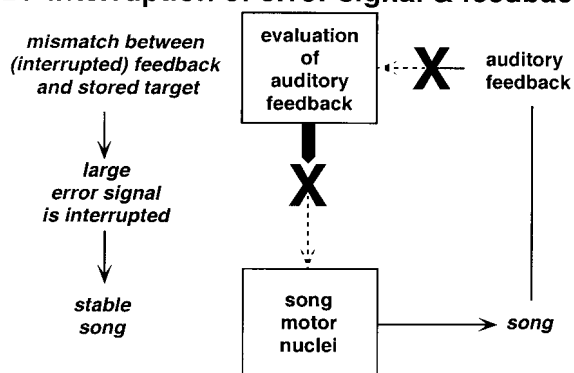

FIGURE 32.2 Hypothetical flow of auditory feedback through the song system and the potential consequences of disrupting that flow at different stages. (A) During song learning, auditory feedback from the developing song of juvenile birds is compared with a stored song target (or template). Differences between the bird's own song and the target song result in an error signal that drives adaptive modification of song. (B) After song learning in a normal adult bird, the bird's own song closely approximates the target song. Consequently, there is little or no

error signal to drive further changes in song, and song remains stable. (C) If auditory feedback is interrupted, then a comparison of feedback with the stored song target will result in a large mismatch and large error signal. This error signal will potentially drive changes in song, which will be nonadaptive. (D) If the error signal itself is interrupted, then the impetus for change in song will be removed, even in the presence of a mismatch between auditory feedback and the stored song target.

BOS that must accompany learning. Moreover, this selectivity emerges during learning. In juvenile zebra finches that have not yet begun to sing, AF neurons respond to all conspecific songs as well as to reversed versions of them. Then, as learning progresses, these neurons rapidly develop strong selectivity for the sounds of the bird's own song, and in some cases for that of its tutor as well (Doupe, 1997; Solis and Doupe, 1997). AF neurons selective for the tutor are well suited to act as a template: They could provide information, encoded in the strength or pattern of their firing rate, about how well certain vocalizations match the memorized song model. Alternatively, AF neurons with selectivity for the bird's emerging song clearly have the potential to provide the developing bird with information about its own vocalizations, which must be a prerequisite for modifying those vocalizations to match the tutor song template. More experiments, including manipulations of this path-

way during song development, will be necessary to test the idea that this circuit provides important sensory or sensorimotor feedback during learning and how it does so. Nonetheless, the developmental studies of its auditory properties provide one line of evidence that it carries information useful in song learning.

Active maintenance of song in adulthood and the function of the AF

Adult song is generally very stable: Repeated renditions of an individual bird's song have highly reproducible acoustic structure. Early experiments, using white-crowned sparrows, also showed that adult song was not affected by deafening, in contrast to the marked disruption of song caused by deafening before or during song learning (Konishi, 1965; Nottebohm, 1968). This suggested that stable adult song becomes completely inde-

pendent of auditory feedback. Recently, however, it has become clear that in some species, auditory feedback is required for adult song maintenance. In adult zebra finches, deafening causes gradual deterioration of song (Nordeen and Nordeen, 1992), while deafening in adult Bengalese finches results in a rapid loss of syllable ordering and a more gradual deterioration of syllable structure (Okanoya and Yamaguchi, 1997; Woolley and Rubel, 1997). This raises the question of whether the mechanisms that subserve normal song maintenance parallel those required during learning. Specifically, is the AF pathway, crucial to learning, also involved in the maintenance of adult song by auditory feedback?

This issue was initially examined by lesioning LMAN bilaterally in normal adult zebra finches, then waiting for weeks to months to see whether interruption of the AF pathway would disrupt song maintenance and result in a gradual deterioration of song similar to that seen in response to deafening. Even 16 weeks after these LMAN lesions, however, song structure remained unchanged (Nordeen and Nordeen, 1993). This indicates that these lesions are not equivalent to removing auditory feedback, and suggests that the AF is not simply a conduit for the auditory feedback utilized in maintaining adult song. These results are consistent, however, with a model in which the AF is involved in evaluating auditory feedback.

The important distinction between these two possibilities is illustrated in figure 32.2, which traces the hypothetical flow of auditory feedback through the song system, and the potential consequences of disrupting that flow at different points. Normally, during song learning, auditory feedback of the bird's own song is encoded by the nervous system and then compared with an internal model of the song target (the song template). To the extent that there is a mismatch between the bird's own song and the song target, the evaluation results in an error or teaching signal that drives adaptive modification of the song motor program (figure 32.2A). After the completion of learning in an adult songbird, auditory feedback matches the song target, and evaluation results in a small error signal that does not cause changes in song (figure 32.2B): At this point the song is stable. Subsequent removal of all auditory feedback, however, causes a large mismatch between expected and actual feedback. This could create a large error signal that drives (nonadaptive) changes in the song (figure 32.2C) such as those seen experimentally in deaf finches (Nordeen and Nordeen, 1992). In contrast, if instead of interrupting auditory feedback prior to its evaluation, the output of the evaluation were interrupted (figure 32.2D), the consequences would be quite different. In this case, no error signal would reach

the motor pathway and song would not change. Indeed, by this hypothesis, interrupting the error signal would occlude the effects of altering auditory feedback (figure 32.2D).

In the context of this model, the failure of LMAN lesions to cause deterioration in song (Nordeen and Nordeen, 1993) indicates that these lesions do not interrupt auditory feedback prior to its evaluation (figure 32.2C). We have begun to test the alternative hypothesis, that the AF participates in evaluating auditory feedback, in a number of ways. In behavioral studies, we compared changes in song that followed deafening with those that followed a combination of deafening and bilateral AF lesions directed at nucleus LMAN (figure 32.2D), to see whether LMAN lesions occlude the effects of deafening. We also recorded neurophysiological activity of the AF in awake birds, to look more directly at the signals present in the AF during singing both in hearing and deaf birds. Preliminary or brief reports of these results have appeared elsewhere (Brainard and Doupe, 1997; Hessler and Doupe, 1997, 1999; Hessler, Kao, and Doupe, 1998).

LMAN lesions occlude the effects of deafening in adult finches

Consistent with prior reports (Nordeen and Nordeen, 1992), we found that songs of normal adult zebra finches were stable over long periods of time, while songs of zebra finches deafened in adulthood gradually deteriorated over a period of weeks to months (figure 32.3A). In marked contrast, songs of birds that received AF lesions at the same time as they were deafened remained relatively unchanged (figure 32.3B).

The effects of experimental manipulations on song were characterized using two separate measures. First, we used human observers to score how well syllables that were initially present in the bird's repertoire were preserved in later songs (similar to the procedures of Morrison and Nottebohm, 1993; Nordeen and Nordeen, 1992). Observers based their judgments on spectrographic representations of syllables that were presented individually. This measure therefore emphasized changes in the phonology of syllables rather than changes in the sequence in which syllables were sung or in the overall temporal pattern of song.

Figure 32.4A summarizes the changes in syllables observed for the different experimental groups. The presongs for each comparison were recorded just prior to experimental manipulation from birds that were at least 3 months of age and had mature songs as judged by the presence of stereotyped sequences of syllables ("motifs") that did not vary from one song rendition to the

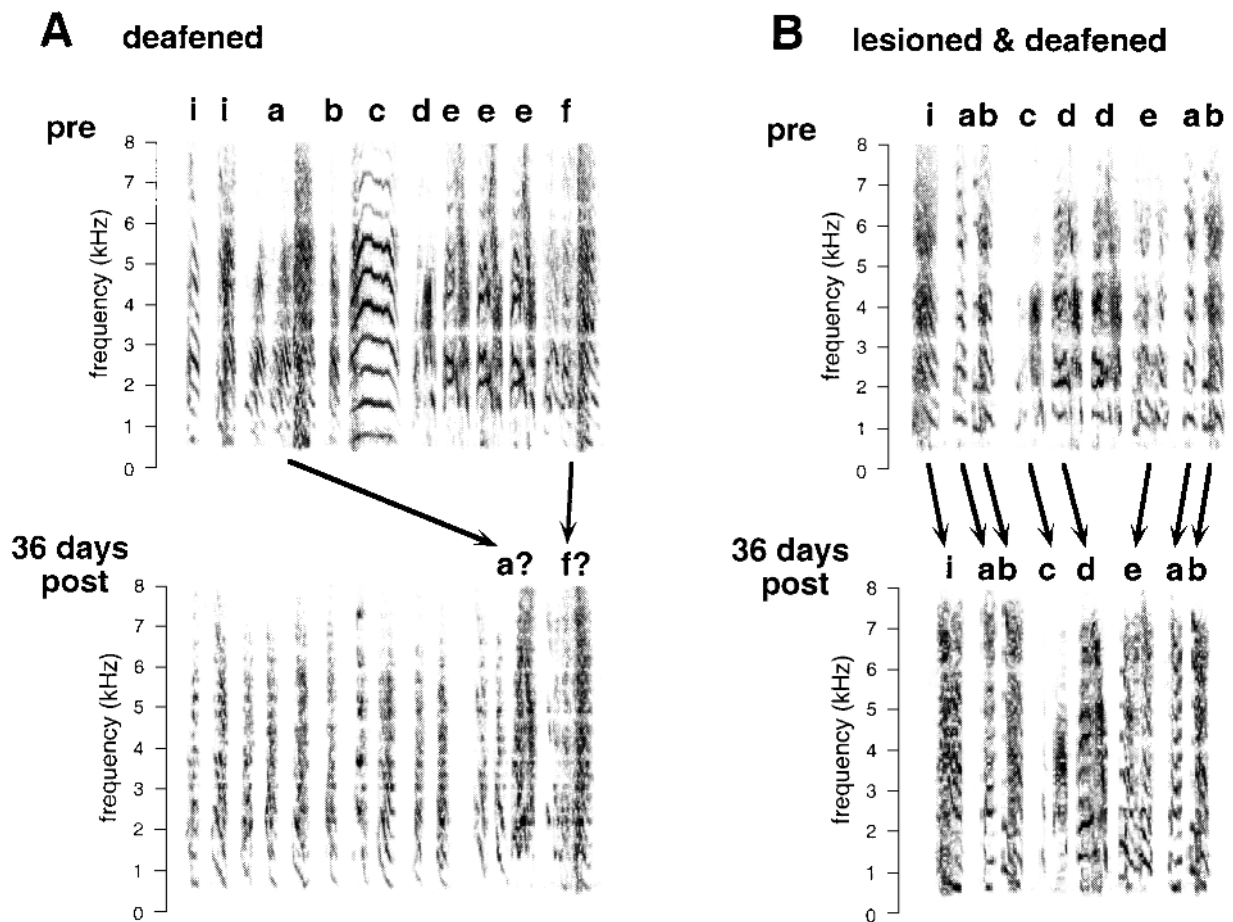

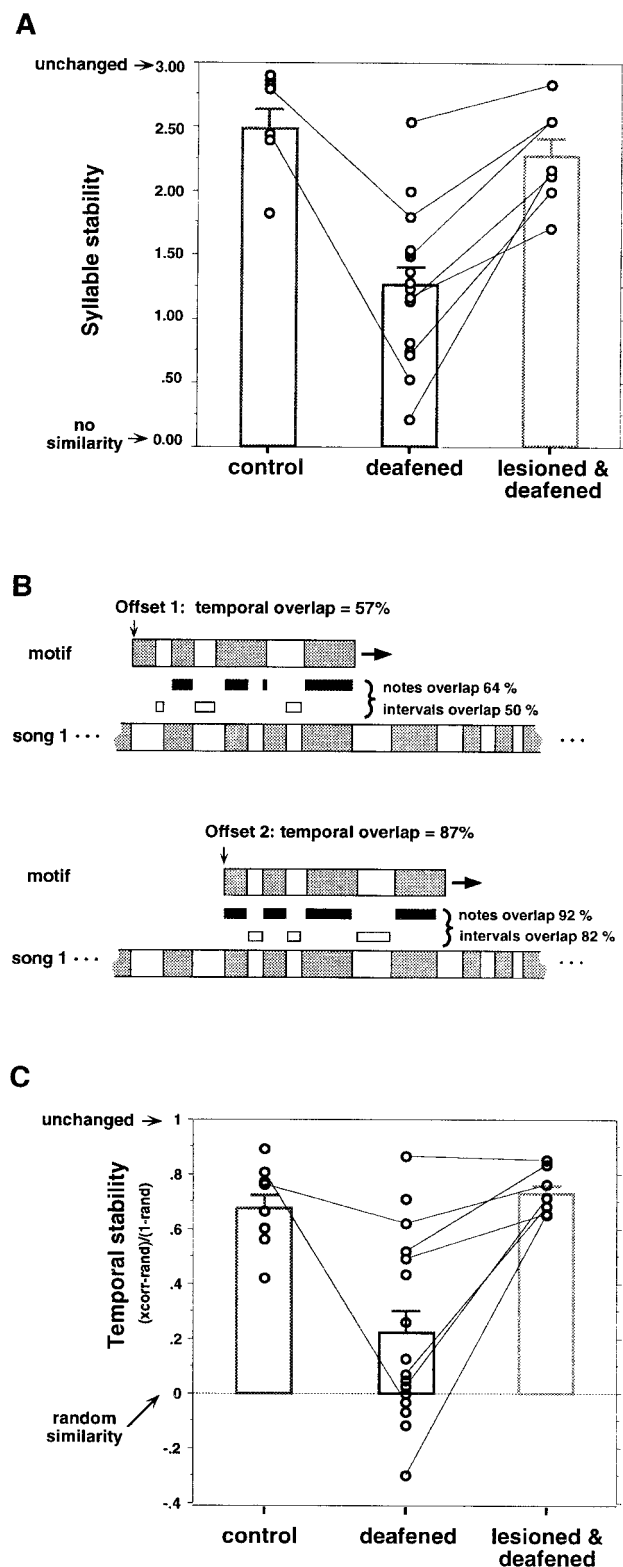

FIGURE 32.3 Effects of deafening on the songs of normal and LMAN lesioned zebra finches. Spectrographic representations of songs recorded at 98 days of age from two normally reared zebra finch brothers. One brother (A) was deafened by bilateral cochlear removal at 107 days of age. This bird's song subsequently deteriorated rapidly, so that by 36 days post-deafening few, if any, of the syllables that had initially been

present in the bird's repertoire were retained. The temporal pattern of song is also clearly altered. The second brother (B) was also deafened at 107 days of age. However, four days prior to deafening, this bird received a bilateral electrolytic lesion of nucleus LMAN. In contrast to the bird that had been deafened only, this bird recognizably retained all of the syllables that initially had been present in its song.

next. The postsongs were recorded at least 200 days later in order to allow maximal effects of deafening to develop. The changes in song that followed deafening varied between individuals, and for some birds were no greater than those observed in controls that retained normal hearing. Sources of this variability may include the age at which birds were deafened, the exact conditions under which they were housed, and the complexity of their songs. In some instances we were able to control at least partially for these sources of variability, as well as for any genetic contributions to variation, by studying pairs of brothers. Brothers were housed together throughout the course of the experiment and had similar songs by virtue of exposure to each other and to the same adult tutor. Additionally, all recordings and shared experimental manipulations for brothers were carried out at the same ages. Data that derive from pairs of brothers are connected by lines in figure 32.4. Despite

the variability in the effects of deafening, overall the songs of deafened birds deteriorated significantly relative to those of controls. In contrast, the songs of birds that received LMAN lesions prior to deafening did not change any more than those of control birds. Furthermore, in each instance where there were recordings from pairs of brothers, the syllables of the birds lesioned prior to deafening were more stable than those of their deafened but unlesioned brothers. Thus, the absence of LMAN largely prevented the phonological deterioration normally resulting from deafening in adult zebra finches.

Second, we used a cross-correlation technique to measure changes in the temporal pattern of songs. For this measure, songs were represented by the timing of the start and end of each syllable while the spectral structure of individual syllables was ignored. For each bird, the timing pattern representing the most common motif before any experimental manipulation was first

identified. Songs from later recording sessions were then searched for the pattern of notes and intervals that most closely matched this motif pattern (figure 32.4B). The best matches for at least 10 songs were then averaged together and normalized (see legend) to yield a

FIGURE 32.4 Summary of song stability following deafening of normal or LMAN-lesioned birds. (A) Syllable stability. Observers that were blind to the experimental manipulation of each bird scored the similarity between syllables from songs recorded before any manipulation and those recorded from later songs. For each “presyllable” initially present in the bird’s repertoire, observers identified the most similar syllable present in songs recorded at later dates. Observers additionally judged the degree of similarity between each presyllable and its best match on a scale of 0 (no similarity) to 3 (identical). Each point corresponds to an individual bird and indicates the average similarity between syllables from presongs and those from songs recorded at least 200 days later. Lines connect points corresponding to brothers housed together and treated identically except for the indicated experimental manipulations. Bars show the means for each group. The syllables of deafened-only birds deteriorated significantly relative to those of control birds. In contrast, syllables of birds that were lesioned prior to deafening did not deteriorate relative to controls. (B) Method for quantification of changes in the temporal pattern of song. Songs were represented by the timing of syllables and intervals (shaded and open boxes, respectively) while the spectral structure of individual syllables was ignored. For each bird the timing pattern representing the most common motif before any experimental manipulation was identified. For each possible offset between the motif and songs from later recording sessions, the degree of temporal match was quantified as the average of the percentage overlap of notes and the percentage overlap of intervals. The temporal overlaps for two separate offsets are illustrated. The regions of note overlap are indicated between the representation of the motif—the songs, by solid boxes and the regions of interval overlap, by open boxes. In this case, the maximal overlap between the motif and the song occurred for the second illustrated offset. This maximal overlap was used as a measure of how well the temporal pattern of song was conserved following experimental manipulation. To partially control for the varying complexity of the motifs sung by different birds, the maximum overlaps for each motif were also calculated relative to randomly selected songs from unrelated birds. The temporal stability of song was then expressed as a normalized value ranging from 0 (equal amount of overlap to unrelated songs) to 1 (perfect overlap). (C) Temporal stability following different experimental manipulations. Each point corresponds to an individual bird and indicates the temporal stability between presongs and songs recorded at least 200 days later. Lines connect points corresponding to brothers. Bars show the means for each group. The temporal pattern of songs for deafened-only birds deteriorated significantly relative to those of control birds. In contrast, songs of birds that were lesioned prior to deafening did not deteriorate relative to controls.

measure of temporal stability. Figure 32.4C illustrates the temporal stability of song observed following the different experimental manipulations. Again, despite a great deal of variability between birds, deafening caused a significant deterioration of the temporal pattern of song relative to controls, and this deterioration was largely prevented by lesions of LMAN. Together with the analysis of syllable structure, these results indicate

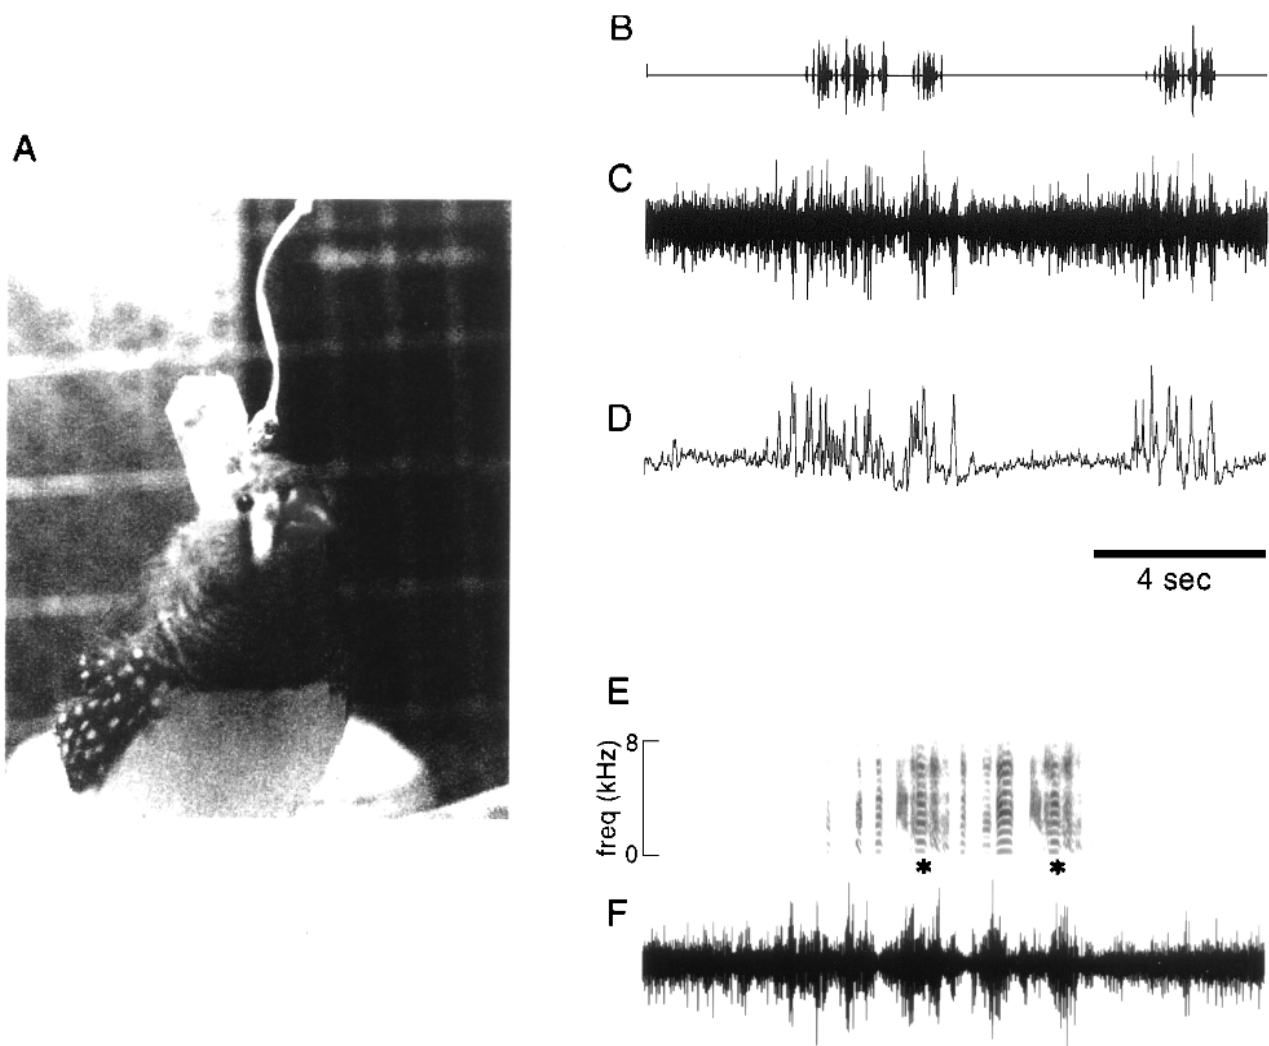

FIGURE 32.5 Neural activity in LMAN associated with song production. The spontaneous vocalizations produced over a period of 10 seconds by a representative bird (A) are displayed as an oscillogram (time-varying amplitude waveform) in B, aligned with simultaneously recorded neural activity in LMAN in C. In D, the waveform of neural activity in panel B has been rectified and integrated, and smoothed with a 10-ms Gaussian kernel, to show the overall pattern of multi-unit activity during singing. The final 4 seconds of singing and associated neural

that lesions of LMAN block vocal plasticity in adult birds, both of syllable phonology and of the overall temporal pattern of song.

LMAN is active during singing in adult birds

To characterize signals present in the AF of normal adult birds, and to determine what has been removed in AF-lesioned birds, we recorded single- and multi-unit activity in LMAN and area X during singing in 20 adult zebra finches. Chronic electrodes were stereotactically implanted in the brain above LMAN and area X, and advanced into the nuclei during recording sessions. In

activity are shown expanded in E and F; the spectrogram in E shows the complex temporal and spectral structure of the bird's vocalizations, and the neural activity waveform highlights the characteristic bursty character of singing-related firing. The asterisks indicate a complex syllable repeated twice in this bout of song: Note that although the acoustic production is very similar, the neural activity associated with each rendition of this syllable is different in pattern.

both LMAN and X, neurons fired vigorously during singing (figures 32.5 and 32.6). Strikingly, excitation began prior to song output, indicating that at least some of the activity is independent of refferent auditory feedback of the bird's own voice. Neural activity in LMAN was also often markedly reduced immediately following song termination.

For a more detailed examination of the relationship of neural firing to song production, we recorded extended periods of singing, during which most birds produced multiple renditions of a stereotyped song. The bird shown in figure 32.7, for example, frequently sang a song type that contained two repeats of an extremely

FIGURE 32.6 Excitation in area X during song production. Spectrogram of a 10-second period including a song produced by bird mx-13 (A), along with simultaneously recorded firing of a single unit in area X (B). This neuron strikingly increased

its firing rate, from a steady baseline of ~ 100 Hz during song production. This can also be seen in panel C, where the instantaneous spike rate of this neuron, calculated by convolving spike arrival times with a 10-ms Gaussian kernel, is displayed.

reproducible five-syllable motif (figure 32.7A–C; note especially the apparent close match between the renditions of the complex syllables d and e in the first and second motifs). The amplitude envelopes of 100 of these song productions are displayed on a grayscale and aligned for maximal overlap of the last four syllables in figure 32.7D. The timing of syllable production over repeated motifs was very stereotyped: For both the first and second motifs, variability in motif duration was approximately 1% [for the first motif, duration = 721 ± 8.2 ms (s.d.); for the second, duration = 736 ± 7.8 ms]. The apparently larger scatter in timing for the first motif is largely due to variability in the interval between the two motifs. Below the 100 motif renditions, the multi-unit neural activity level recorded in LMAN during each song is also plotted on a grayscale (figure 32.7E). This makes evident the consistent increase in neural activity prior to the first song elements as well as the post-singing inhibition.

In addition to the relationship between activity and the initiation and termination of singing, there were on average in all recordings consistent patterns of activity related to individual song elements. Although this was not always obvious on single trials or with single units (e.g., figures 32.5E–F and 32.7G), it can be seen in a plot of average activity level during song motifs (figure 32.7F): Even though syllables in the first motif are not optimally aligned, the patterns of average activity are quite similar during, for example, the repeats of syllables d and e in the first and second motifs. When both motifs

were independently well-aligned, mean activity levels during repeated song elements were even more similar. Thus, despite the variability across renditions at the single-neuron level, the simultaneous activity of multiple AF neurons carries a signal with a consistent relationship to song syllables.

Peaks of activity in all recordings also tended to precede syllables (figure 32.7D–E; see also figures 32.10 and 32.11). To compare directly the temporal relationship of activity to song production for LMAN with that in the motor pathway, we calculated the latency from increased neural activity to song onset. For a representative bird, activity preceding 84 song bouts in which the bird had been quiet for at least three seconds prior to singing is displayed in figure 32.8. Firing to song onset latency was measured from the onset of the abrupt activity peak just preceding the first syllable of the song to the onset of this syllable (some birds, like the one in figure 32.8, also showed a slow and variable increase in activity prior to the distinct activity peak, which was not included in this latency measurement). For the site shown, the mean latency was 58 ms; across recordings from all birds, the mean latency was 62 ± 16 ms (s.d.), with means within individual birds ranging from 48 to 95 ms. These values are in the range of those reported in previous studies of singing-related activity in HVC (McCasland, 1987; Yu and Margoliash, 1996). This is therefore consistent with the possibility that much of the singing-related AF activity originates from the song motor circuit, and may represent in part a version of the

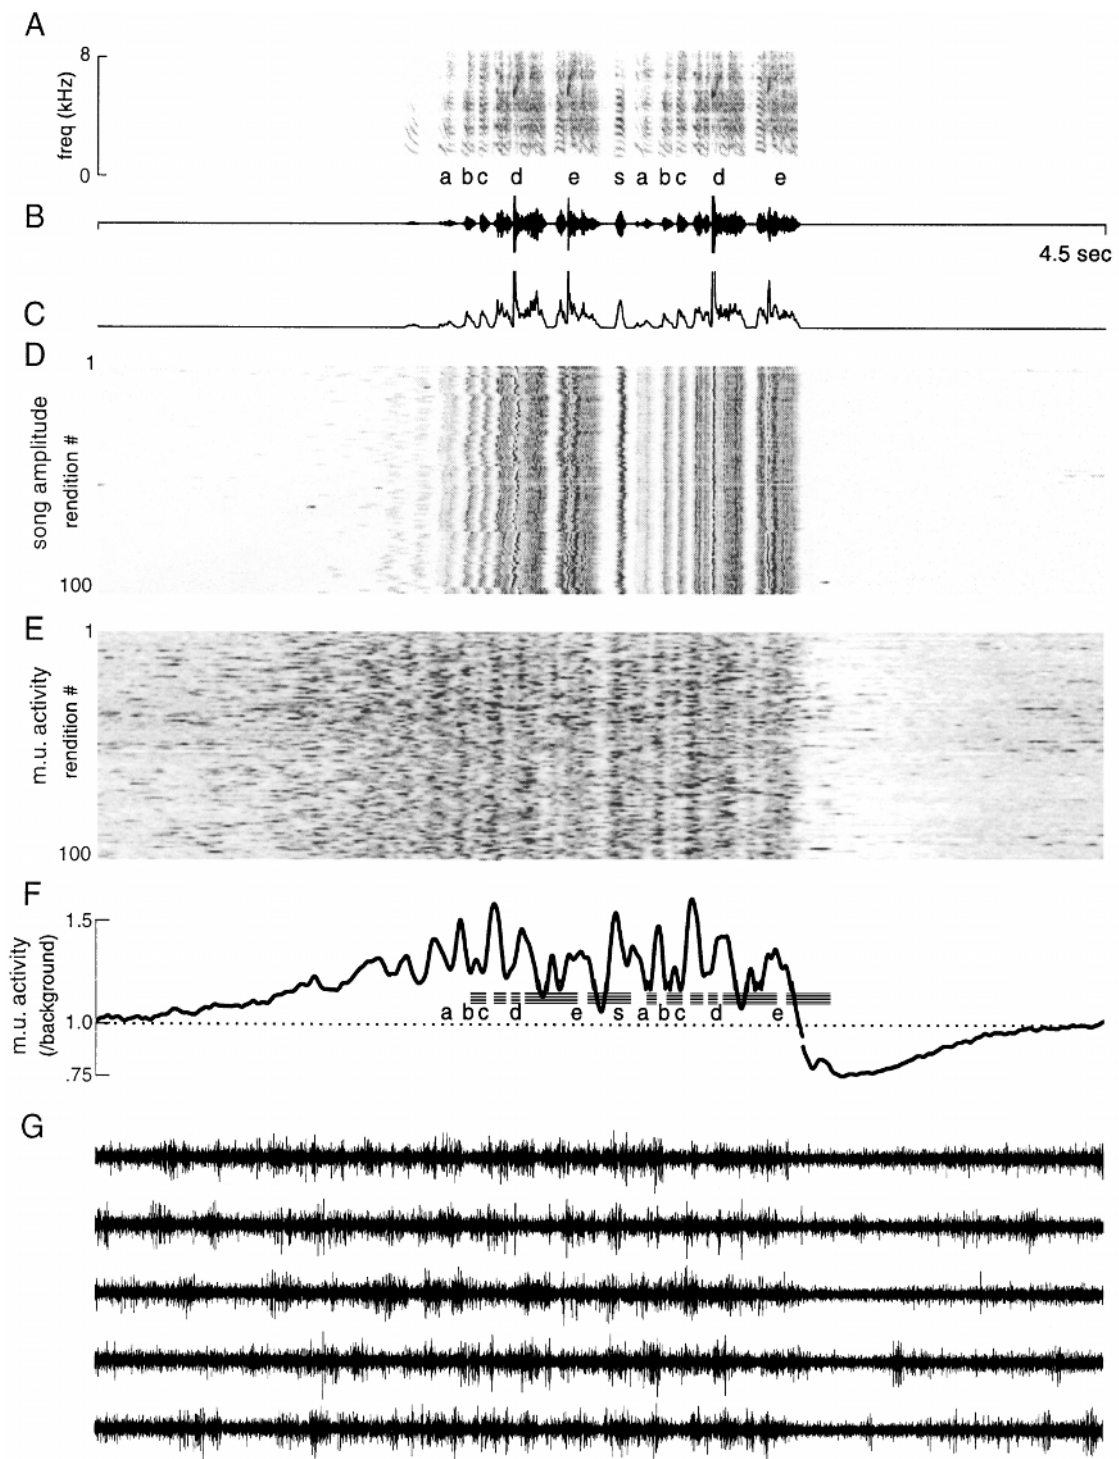

FIGURE 32.7 Neural activity in LMAN associated with repeated song-motif renditions. Spectrogram (A) and oscillogram (B) of a typical song produced by bird dc-18. In order to represent song temporal structure in one dimension, the song oscillogram waveform was rectified and smoothed, as shown in C. These smoothed amplitude envelopes can then be displayed using a grayscale (dark areas represent high intensity), allowing a graphical representation of multiple song renditions, as in D, in which amplitude envelopes of 100 consecutive song renditions recorded in a single session are plotted,

aligned for maximal overlap between the final four syllables. The striking stereotypy of song timing and structure is evident in these plots. Panel E shows the multi-unit neural activity level recorded during each successive song rendition, along with F, the mean neural activity level (normalized by background nonsinging activity level) across 160 song renditions. Mean timing of syllable occurrence is overlaid on panel F for comparison of activity to song production. Neural activity during five representative song renditions is shown in panel G.

FIGURE 32.8 Temporal relationship of LMAN firing to song initiation. (A) Multi-unit activity level, represented in gray-scale, as in figure 32.7, during multiple 2-second presinging epochs, and the initial 200 ms of singing. (B) Below activity levels for individual trials is plotted the mean of all trials, scaled by background activity level. Note the slight and gradual increase in activity several hundred milliseconds prior to song and the abrupt activity peak just prior to singing onset. The onset of this peak, at 58 ms prior to song initiation, is indicated by an asterisk.

premotor signals also sent to the motor output pathway, that is, an “efference copy” of motor commands from the song control nucleus HVC. Such activity patterns are often seen in sensorimotor systems (von Holst and Mittelstaedt, 1950; Bell, 1989; Bridgeman, 1995) and can be useful for providing information about intended motor activity to multiple areas of the brain, and for comparing motor commands with the motor or sensory consequences of these commands.

As an initial investigation of what portion of the activity during singing might reflect sensory input—and because most previous studies of the AF analyzed auditory responses to playback of song (although in anesthetized birds)—we also presented a taped version of the bird’s song to awake birds. Playback of the bird’s own song did in some cases evoke patterned activity similar to that seen in anesthetized birds. One of the strongest such responses that we recorded is shown in figure 32.9. Passive presentation of a two-motif song consistently elicited increases and decreases in multi-unit neural activity (figure 32.9B,C) at this site. This response was clearly smaller, however, than that seen at the same site when the bird produced the same song motif itself (figure 32.9D–E), and a clear relationship between the firing pattern during singing and that during playback was not

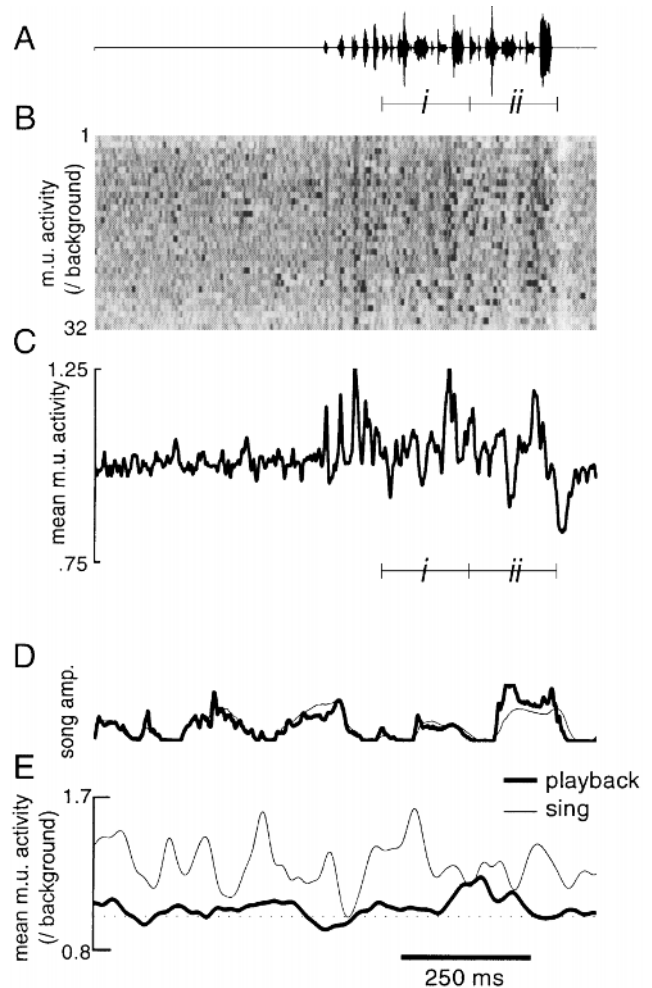

FIGURE 32.9 LMAN activity elicited by presentation of a bird’s own song and comparison to singing-related activity. Multiple trials of passive presentation of a two-motif version of a bird’s own song (A; motifs denoted by i,ii and divided by bar) elicited consistent firing (B) over background levels, as measured by integrated multiple unit activity (grayscale axis: darkness proportional to amplitude). Consistent firing pattern over presentations is indicated by distinct peaks and troughs in the mean activity level (C; scaled by background firing level) over these presentations. Despite the equal overall amplitude of the two songs (D; thin line, average amplitude of motifs sung; thick line, average amplitude of taped song), mean activity levels during playback of the first and second motifs combined (E; thick line) were lower than the activity elicited during singing of the same song motifs at the same site (E; thin line, average multi-unit activity level).

apparent. Such playback responses were not seen in all birds, and were in all cases less consistent than activity during song production. Thus, much of the singing-related firing may be associated with motor production of song, and it may also be critical for maximal and consistent sensory responses that the bird produce the sound itself.

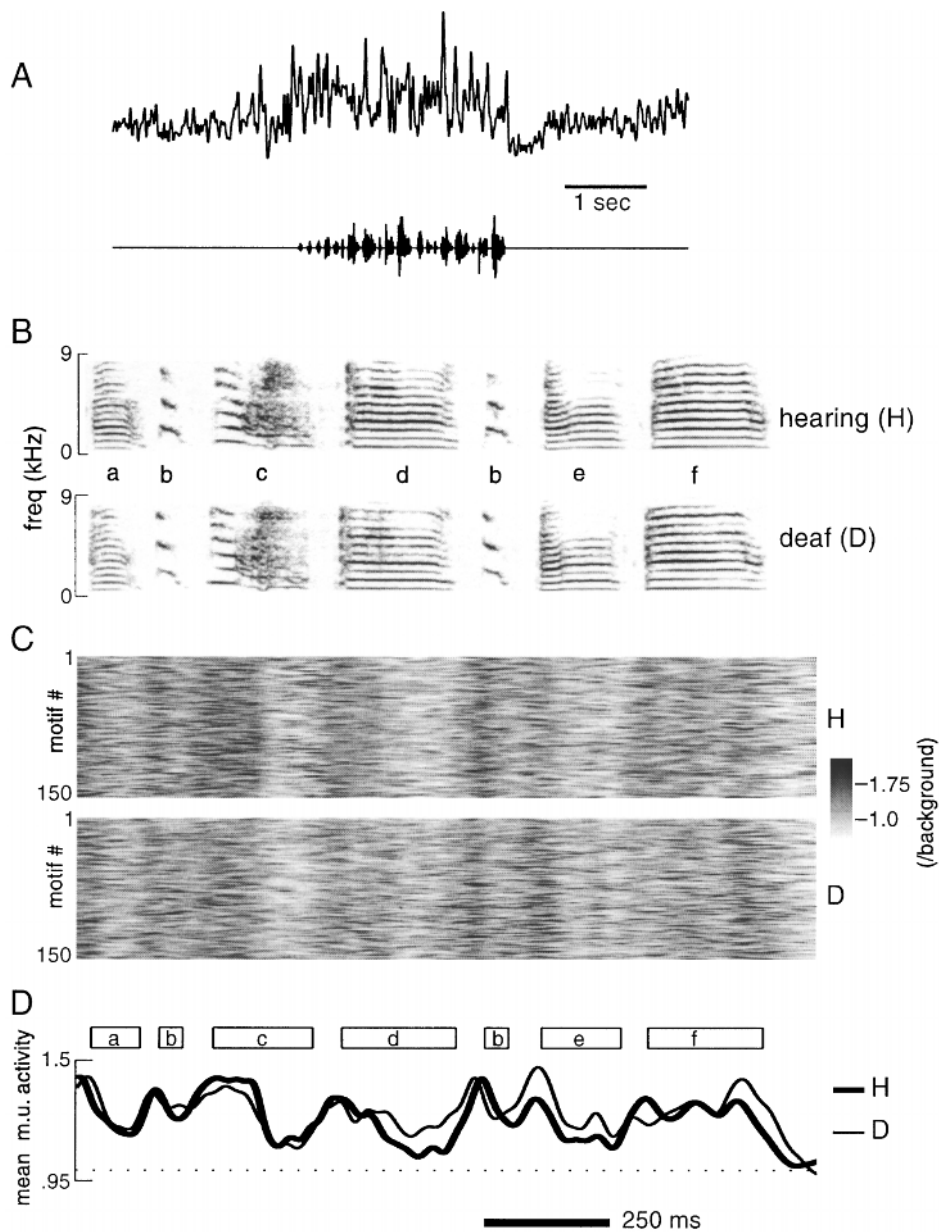

FIGURE 32.10 Singing-related neural activity at sites in LMAN before and after deafening. (A) The waveform and oscillogram show the song and associated increase in LMAN firing in a deaf bird. Between several hours prior to deafening (H) and one day following deafening (P.D.), the production of a stereotyped seven-syllable song motif was not grossly altered. (B) Multi-unit neural activity level (normalized by background nonsinging activity levels; see grayscale to right) in LMAN during repeated motif renditions was likewise very similar in pattern and amplitude between hearing (H) and

deafened (P.D.) conditions, despite the fact that this activity was recorded at different sites in the hearing and deaf birds (C). Furthermore, mean activity levels across 150 motif renditions (D) revealed only small differences in the pattern of activity during motif production between the site at which the bird could hear its own voice and the site recorded when it could not. Above the mean activity plot is a representation of the average syllable timing (for the P.D. recording). Note that, as in figure 32.11, the trend for peaks of activity seems to associate with syllable onsets.

AF nuclei are active during singing in deaf birds

To determine whether activity is present in the AF of deaf birds, we recorded multi-unit activity from several sites in LMAN, deafened the birds by cochlear removal, then recorded activity during singing one to three days

later. The nucleus was still markedly active during singing (figure 32.10A), and thus AF activity is available to influence the song motor pathway of deaf birds.

We then began to investigate whether AF activity is not only present after deafening but immediately altered in its patterning. As an initial attempt to examine

whether patterned AF activity during song production is modulated by the sound of the bird's own voice, we compared the pattern of multi-unit activity during motifs recorded from deaf birds (at a time when song structure had not yet noticeably changed, 1–4 days post-deafening; figure 32.10B) to that recorded at nearby sites before deafening. Strikingly, neither the activity of multi-unit sites (figure 32.10C) nor the activity averaged over many sites (figure 32.10D) was grossly different between pre- and post-deafening recordings. Thus, on average, much of the singing-related AF firing is not dramatically or rapidly altered by deafening. If the sensory feedback from the bird's own voice is of the same order of magnitude as responses to playback (figure 32.9), however, it might be a small fraction of the large singing-related neural activity, and perhaps difficult to detect under normal conditions. More precise measurements of activity of the same sites or even single neurons pre- and post-deafening will be necessary to see if the AF activity of identified neurons or sites shows any immediate, more subtle, alterations in the absence of auditory feedback. In addition, systematic and reversible manipulations of auditory feedback that alter its correlation with singing, rather than simply removing it, may be more useful than deafening for revealing any influence of sounds heard on AF activity. Finally, since song deteriorates very slowly in these birds, it may be that, although auditory feedback changes immediately, the neural implementation of the error signal emerges only gradually in adult finches.

AF activity is modulated by social context

Social factors are critically important to singing, both during song learning and in adult song production. For example, a number of studies have shown that zebra finches will not learn from tutors unless they can interact with them (visually or physically; cf. Slater, Eales, and Clayton, 1988); similarly, they have not been found to learn from tape playback unless they are trained to activate the tapes themselves (Adret, 1993). In adult zebra finches, both singing and overall behavior differ when males sing to a live female or male of the same species, as compared to singing in isolation. The songs in these two situations, which have been called “directed” and “undirected” song, respectively, have been suggested to differ in some way in motivational intensity. We investigated whether the singing-related AF activity of adults might be similarly modulated by social context.

For eight birds, epochs of spontaneous isolated singing were interspersed with presentation of a female or male zebra finch, in a separate cage, to the recorded male. Most birds began singing to the other bird within

seconds. Although in a previous study, directed song motifs were sung more rapidly than undirected ones (Sossinka and Bohner, 1980), we did not consistently observe this in our experiments: Our birds' directed song sped up at most by 1%. Syllable structure also did not differ detectably between the two conditions (figure 32.11, top). Thus, the fine structure of motif production was nearly identical for these songs produced in quite different behavioral contexts.

The pattern of neural activity in anterior forebrain nuclei, however, was strikingly dependent on the behavioral context. One example of such an experiment is seen in figure 32.11. During an eight-hour recording session, almost three hundred renditions of a stereotyped six-syllable song motif (figure 32.11, top) were produced. The multi-unit activity level in LMAN during each rendition, plotted on a grayscale as in figures 32.7–10, is shown beneath the spectrograms in figure 32.11. The responses occurred in two distinct social contexts, either with another bird present (filled bar to right of activity plots), or in isolation (empty bar to right). The pattern of activity during production of identical song elements clearly depended on whether the bird was alone or with another bird. Average activity during singing directed to another bird was consistently of lower overall amplitude, as is seen in the mean activity levels within and across renditions (figure 32.11). Moreover, there was a larger modulation of activity during undirected compared to directed singing, as measured by the coefficient of variation (C.V.) of activity levels within individual song renditions (figure 32.11, *within rendition* panel). Finally, the activity patterns during the two conditions revealed more variability in the pattern of activity associated with song elements during undirected as compared to directed singing (as measured by the C.V. values across motif renditions for each condition; figure 32.11, *across renditions* panel). Many of these differences between the two social conditions can be seen not only in the mean activity plots, but also in traces of neural activity such as those recorded during six consecutive motif renditions, spanning a transition from accompanied to solitary social state (figure 32.11, bottom). Spikes during directed singing (the top three waveforms) often appeared discrete and temporally distinct from each other, while firing during singing alone (bottom three waveforms) was often clustered into large bursts of activity, which could be followed by depression below background firing levels. Similar differences in activity were seen between directed and undirected singing for six birds in LMAN, and for five birds in area X. Thus, AF firing is consistently different in distinct social settings.

While AF activity distinguishes between directed and undirected singing in adult birds, preliminary results

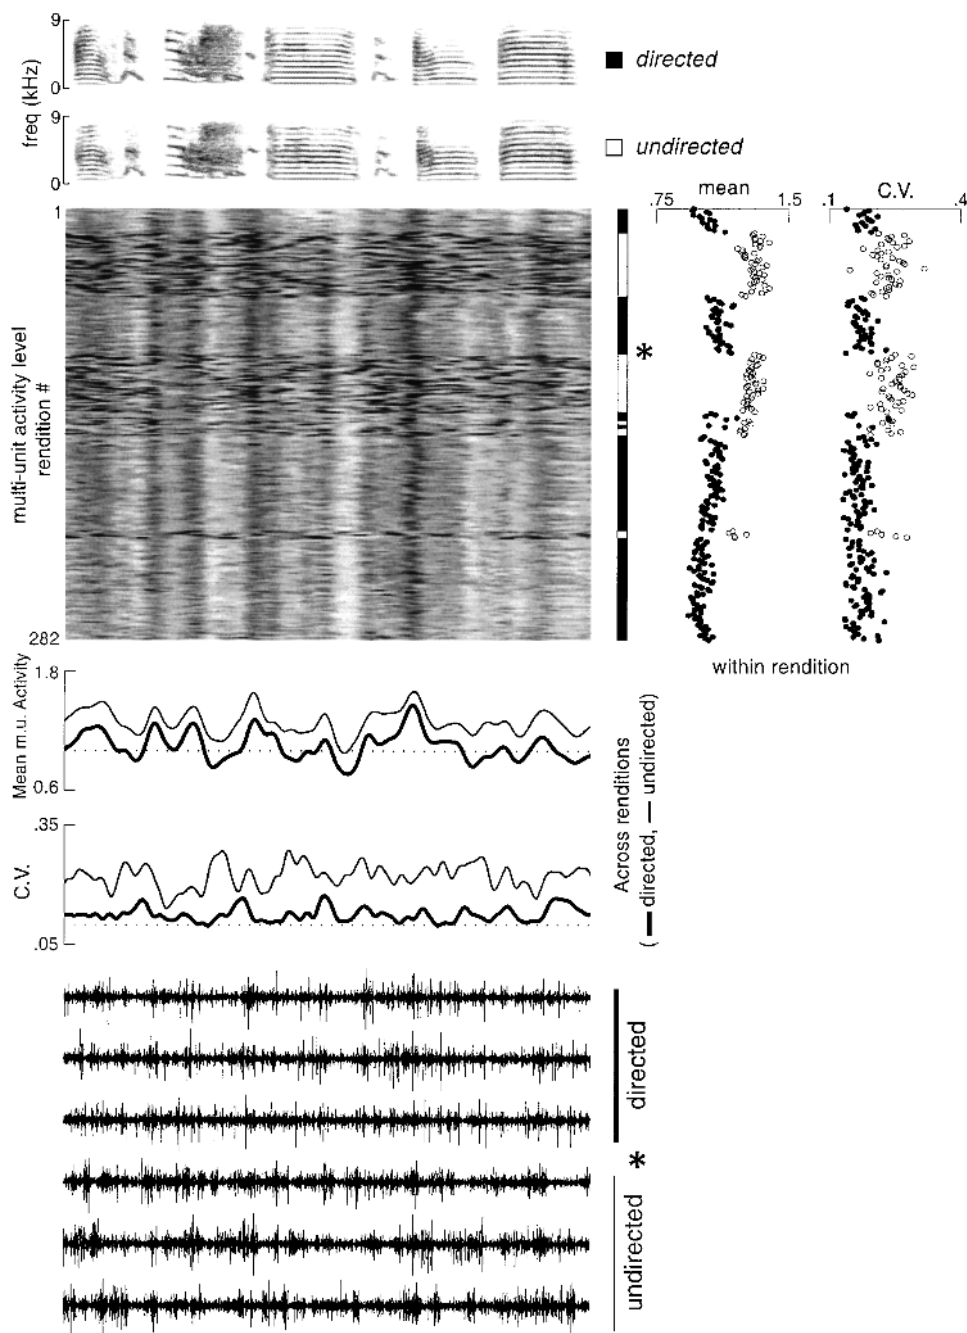

FIGURE 32.11 Firing in AF nuclei is strongly modulated by social factors. Top: Spectrograms of a six-syllable song motif of bird dc-12, sung in the presence of another bird (above, *directed*) and in isolation (below, *undirected*). Plotted below these spectrograms is the multi-unit neural activity recorded during production of consecutive renditions of this motif during an eight-hour session, with amplitude represented by grayscale, as in figures 32.7 through 32.10. Duration of each rendition is 950 ms. The vertical bar to right of the panel indicates social stimuli present during production of each motif rendition, with the filled bar representing the presence of another bird (directed singing), and the empty bar representing isolation (undirected singing). To the right of the social status bar are plotted the mean activity level for each motif rendition and the relative

modulation level of activity within each motif (calculated as the C.V. of activity within each rendition, that is, the S.D./mean). Note the strong and reproducible difference in activity during song depending on the behavioral context. Panels below the grayscale activity panel show the mean activity levels and the C.V. of activity over time across all renditions of directed (thick line) and undirected (thin line) motifs. Background levels of mean activity and C.V. are plotted as dotted lines on these panels. Bottom: Neural activity waveforms recorded during production of six consecutive song motifs during a change from directed to undirected singing (these waveforms were drawn from the epoch marked with an asterisk to right of social context bar).

suggest that the direct motor circuit of the adult song system may not (Hessler, Kao, and Doupe, 1998). In recordings of multi-unit neural activity in the nucleus RA of three adult zebra finches, there were no significant differences in firing amplitude or variability between directed and undirected singing. This is consistent with the relative lack of difference in song structure between the two types of singing in our experiments. Thus, the signal influencing the activity of the song system AF circuit as a function of social context may arise elsewhere than HVC, perhaps in the strong projection from mesolimbic dopaminergic neurons to the AF circuit (Lewis et al., 1981; Soha, Shimizu, and Doupe, 1996).

Conclusions

Although initial lesion studies of the AF nuclei suggested that they play a role only during song learning (Bottjer, Miesner, and Arnold, 1984; Nottebohm, Stokes and Leonard, 1976; Scharff and Nottebohm, 1991; Sohrabji, Nordeen, and Nordeen, 1990), this idea must be revised in light of these behavioral studies of adults in whom the normal match between song output and its feedback has been altered. They show that the nucleus LMAN is also essential in adults for vocal motor plasticity, even the marked deterioration associated with deafening. This is consistent with the results of Morrison and Nottebohm (1993), who created an unusual situation in which adult zebra finches could incorporate new syllables into song, and showed that they did not do so after LMAN lesions.

In addition, our neurophysiological studies in awake, behaving birds show that singing is accompanied by patterned activity in the AF, even though this activity is not required for song production. This activity is present in both hearing and deaf adult birds during singing, and thus may provide information necessary for plasticity to the motor pathway. The temporal relationship of AF firing to song suggests that this activity consists in part of an efference copy of the motor commands from the song control nucleus HVC. Finally, singing-related activity in LMAN and area X is also modulated by behavioral context, which is known to be important for song learning in zebra finches: When birds sing to conspecific males or females, AF activity during song is decreased both in magnitude and in variability compared to activity in the same birds singing alone.

In combination, the behavioral and physiological results suggest that the AF provides a neural error signal that actively instructs change in the motor pathway of birds experiencing a sensorimotor mismatch. This “instructive” model for the function of the AF in adult song maintenance, equivalent to the ideas outlined in figure

32.2, is thus the same as that proposed for young birds. Alternatively (or in addition), AF activity may be “permissive” for plasticity by providing critical neural or trophic inputs to the motor pathway. Several lines of evidence offer indirect support for the first (instructive) hypothesis. For one, the AF is clearly active during singing, even in deaf birds, and thus provides input to the RA premotor neurons also receiving direct input from HVC. Moreover, the song-selective auditory properties of neurons in LMAN and area X are well suited to provide feedback to the motor pathways about how well a bird’s vocalizations match its intended target (Doupe, 1997; Solis and Doupe, 1997). Surprisingly, however, the overall activity in LMAN during singing did not immediately change dramatically between hearing and deaf birds. Further crucial predictions of this hypothesis therefore remain to be addressed, particularly whether the patterned activity of the AF during singing carries sensory information about the bird’s own vocalizations, and whether this changes, perhaps subtly or slowly, in singing birds with sensorimotor mismatch.

Alternatively, the hypothesis that LMAN is permissive for change in song output throughout life proposes that, without LMAN inputs to RA, no change in the connections of the motor pathway (HVC to RA and RA intrinsic connections) can occur. The occlusion of the effects of deafening by LMAN lesions in this model would be the result of withdrawing inputs necessary for plasticity from RA. The putative error signals resulting from sensorimotor mismatch might exist elsewhere in the song circuit, or could also be in the AF; in the latter case, the AF would be instructive as well as permissive. Several existing findings are consistent with the idea that the AF is permissive for vocal plasticity. In young birds, lesions of LMAN have very different effects on song than do lesions of the AF nucleus two steps earlier in the pathway, area X (Scharff and Nottebohm, 1991; Sohrabji, Nordeen, and Nordeen, 1990). Following lesions of area X, the song of young birds remains permanently plastic, perhaps as a result of losing an instructive target signal. In contrast, LMAN lesions in birds of the same age cause a rapid and premature crystallization of an abnormally simplified song. This behavioral difference suggests that area X and LMAN lesions do not cause completely analogous disruptions of patterned information through this pathway, and that LMAN lesions in young birds cause decreased vocal motor plasticity just as in adults. One possibility is that loss of LMAN terminals deprives RA not only of patterned activity, but also of some neural or trophic influence required to change synapses in the motor pathway. Earlier in development (around 20 days posthatch in zebra finches), LMAN clearly has some trophic function, since

lesioning LMAN results in cell death in RA (Akutagawa and Konishi, 1994; Johnson and Bottjer, 1994). In addition, in both juvenile and adult birds, the LMAN synapses on RA neurons activate primarily NMDA receptors, rather than the more usual mixture of NMDA and non-NMDA receptors common in most forebrain areas (Mooney, 1992). Such highly NMDAergic synapses are common in developing systems, where their activation and the subsequent influx of calcium is thought to play a trophic role in synaptic growth and stabilization (e.g., Constantine-Paton, Cline, and Debski, 1990), but are much rarer in adults; the presence of significant numbers of such synapses in adult RA makes them a possible candidate for mediating trophic or other permissive effects of LMAN activity.

Finally, song learning in general, and in zebra finches in particular, is strongly dependent on particular behavioral cues, and can be shaped by social factors, both early, during sensory learning (Adret, 1993; Baptista and Petrinovich, 1986; Slater, Eales, and Clayton, 1988), and later, during song crystallization (West and King, 1988; Nelson and Marler, 1994). The consistent change in AF firing in different social settings thus raises the possibility that the AF can regulate song plasticity as a function of behavioral context, and/or contribute to motivational and social aspects of song. The fact that neither song structure nor RA activity in adults appeared to change acutely in response to the socially induced changes in LMAN activity is similar to the slow or absent effects of deafening and LMAN lesions on adult song. This may reflect the weak effect of the LMAN to RA connections in adult birds, which are much diminished compared to those in juvenile birds (Herrmann and Arnold, 1991). Social effects on song and RA neural activity might be much faster and more obvious in young birds, when plasticity is enhanced. Alternatively, social effects on song structure and learning at any age may occur slowly over time and require multiple episodes of a particular behavioral context.

These studies in adults, at a time when the rapid growth and development of the song system is complete and no longer confounds the mechanisms essential to learning, have provided evidence for a role of the AF pathway in vocal plasticity that holds throughout learning as well as in adulthood. Moreover, the problems of social and attentional effects on learning, which are evident in many animals, may be particularly approachable in this system, with its combination of a discrete behavior and a dedicated neural circuit involved in its control.

ACKNOWLEDGMENTS We thank Tony Movshon for comments on the manuscript, Amy Tam and Adria Arteseros for

expert technical help, and Ned Molyneux for excellent editorial assistance. The work described and the preparation of the manuscript were supported by a Life Sciences Research Fellowship (MSB), a National Research Service Award (NAH), the Merck Fund, the EJLB Foundation, and National Institutes of Health grants MH55987 and NS34835.

33 A Computational Model of Avian Song Learning

KENJI DOYA AND TERRENCE J. SEJNOWSKI

ABSTRACT Oscine song learning has an auditory phase during which a tutor song is learned and a sensorimotor phase of successive improvement that leads to adult song. A theoretical framework for song learning is presented based on the hypothesis that the primary role of the *anterior forebrain pathway* of the song system is to transform an auditory template to a motor program by a form of reinforcement learning. This framework was tested by building a network model of the song-learning system including a model of the syrinx, the avian vocal organ. The model replicated the spectral envelopes of the syllables from zebra finch songs after several hundred trials of learning. The performance of the model was even better when trained on songs generated by another model having the same architecture. Experiments are proposed to further test the biological plausibility of the hypothesis, which may lead to a more detailed model of the song-learning system. Other types of sensorimotor learning based on mimicry could be implemented with a similar type of computational model.

In comparison with our understanding of the preprogrammed central pattern generators found in many invertebrates and lower vertebrates responsible for complex motor behaviors (Cohen, Rossignol, and Grillner, 1988; Harris-Warrick et al., 1992; Kristan, 1992), much less is known about the representation of motor patterns acquired through experience in humans and other vertebrates, such as walking, riding a bicycle, or talking. Singing in oscine birds is a favorable system for studying the acquisition of complex motor patterns. Much is known about the ethology of birdsong learning and the influence of early auditory learning (Marler, 1963; Konishi, 1965; Marler, 1991; Catchpole and Slater, 1995). The major brain nuclei involved in song control and learning have been identified, as schematically shown in figure 33.1 (Nottebohm, Stokes, and Leonard, 1976; Bottjer et al., 1989). New data are accumulating from lesion and recording experiments on these nuclei (for reviews, see Konishi, 1985; Doupe, 1993; Margoliash, 1997; Bottjer and Arnold, 1997).

TERRENCE J. SEJNOWSKI Department of Biology, University of California, San Diego, and Howard Hughes Medical Institute, Salk Institute for Biological Studies, La Jolla, Calif.

The primary goal of this chapter is to present a theoretical framework and a working model for song learning based on recent experimental findings. Specifically, we focus on the function of the *anterior forebrain pathway*, which is not involved in song production in adult birds, but is necessary for song learning in young birds (Bottjer, Miesner, and Arnold, 1984). Our main hypothesis is that the anterior forebrain pathway works as a reinforcement learning system that is similar to the *adaptive critic* architecture proposed by Barto, Sutton, and Anderson (1983).

The song *template* is a key concept in birdsong learning. A young male bird listens to a *tutor song* during the *critical period* and memorizes a template of the song; later, the bird learns to sing the stored song by comparing its own vocalization to the song template using auditory feedback (Konishi, 1965). However, it is still an open question how the song is encoded and where in the bird's brain the song template is stored. Recent experiments in zebra finch suggest that the song control system has a hierarchical organization: HVC, the high vocal center, is involved in producing a sequence of syllables, whereas its downstream nucleus RA is responsible for the subsyllabic components (Vu, Mazurek, and Kuo, 1994; Yu and Margoliash, 1996).

If we assume that a song is learned in such a hierarchical fashion, the problem of song learning can be decomposed into the following three subproblems:

1. *Sensory encoding*: How to encode the acoustic features of syllables in such a way that they are reliably recognized.
2. *Sequential memory*: How to organize the network so that syllable sequences are stably memorized and reproduced.
3. *Motor decoding*: How to find the motor command patterns needed to replicate the acoustic features of each syllable.

Existing experimental evidence does not provide straightforward solutions to these problems. A computational approach could help in exploring the biological solutions and, in particular, in providing functional

FIGURE 33.1 Schematic diagram of the major songbird brain nuclei involved in song control. The thinner arrows show the direct motor control pathway, and the thicker arrows show the anterior forebrain pathway. Abbreviations: Uva, nucleus uvaeformis of thalamus; NIf, nucleus interface of neostriatum; L, field L of forebrain; HVC, high vocal center (formerly called hyperstriatum ventrale, pars caudale); RA, robust nucleus of archistriatum; DM, dorsomedial part of nucleus intercollicularis; nXIIts, tracheosyringeal part of hypoglossal nucleus; AVT, ventral area of Tsai of midbrain; X, area X of lobus parolfactorius; DLM, medial part of dorsolateral nucleus of thalamus; LMAN, lateral magnocellular nucleus of anterior neostriatum.

constraints on the organization of the learning system. For example, theories of unsupervised learning (von der Malsburg, 1973; Amari, 1977; Linsker, 1986; Bell and Sejnowski, 1995) suggest several possible solutions to sensory encoding problems. Studies of associative memory networks (Fukushima, 1973; Sompolinsky and Kanter, 1986; Dehaene, Changeux, and Nadal, 1987; Amari, 1988; Morita, 1996) provide constraints on representation and architectures that enable stable storage of temporal sequences. There have been extensive studies on the “inverse problem” of finding the control input for a nonlinear system to realize a given target output (Miller, Sutton, and Werbos, 1990; Gullapalli, 1995).

In this chapter, we propose a working hypothesis for the functions subserved by song-related brain nuclei in songbirds (figure 33.1), with an emphasis on the role of anterior forebrain pathway in solving the motor decoding problem.

Figure 33.2 illustrates various schemes for solving inverse problems using neural networks. In the first scheme (figure 33.2a), the desired output is converted to a desired motor command by an inverse model of the motor system that enables replication of the desired output in one shot. Although attractive as a model of vocal learning in other species like

humans, this is not an appropriate model for vocal learning in songbirds because they require many repetitions of singing trials with auditory feedback. Another possible scheme is error correction learning (figure 33.2b) that uses a linear approximation of the inverse model to convert motor output error into the motor command error for incremental learning of the control network. The problem is that the learning schemes proposed to date either use a biologically implausible algorithm (Jordan and Rumelhart, 1992) or assume the preexistence of an approximate inverse model (Kawato, Furukawa, and Suzuki, 1987; Kawato, 1990). Furthermore, in order to calculate the error in the acoustic output, a replica of the target output, or the tutor song, has to be available.

The third scheme (figure 33.2c) is based on the paradigm of reinforcement learning (Sutton and Barto, 1998). It does not use an inverse model and uses a critic that evaluates the motor output by comparing the present vocal output with the tutor song. Learning is based on the correlation between stochastic changes in the motor command and the increase or decrease in the evaluation (Barto, Sutton, and Anderson, 1983; Gullapalli, 1995). There is no need to maintain a replica of the tutor song. Activation levels of auditory neurons that have selective tuning to the tutor song can be used as the evaluation signal.

Among these alternatives, we argue that the reinforcement learning scheme (figure 33.2c) is the most likely for birdsong learning. We will further propose a hypothesis about how this reinforcement learning scheme can be implemented in the known circuitry of the song control system with the constraints given by anatomy, physiology, and the results of lesion studies. We then describe a neural network model that replicates song learning behavior based on these constraints. Experimental tests of the model and limitations are addressed in the “Discussion.”

Earlier versions of this model have appeared elsewhere (Doya and Sejnowski, 1994, 1995).

Model of the song control system

ANATOMY OF THE SONG CONTROL SYSTEM The principal brain nuclei involved in song learning are shown in figure 33.1 (Nottebohm, Stokes, and Leonard, 1976; Bottjer et al., 1989). There are two major pathways: the direct motor pathway and the indirect, anterior forebrain pathway. The direct pathway is composed of Uva, NIf, HVC, RA, DM, and nXIIts. Lesions to these nuclei immediately disrupt singing, although the effects of lesions in Uva and NIf are variable (Nottebohm, Stokes, and Leonard, 1976; Mc-

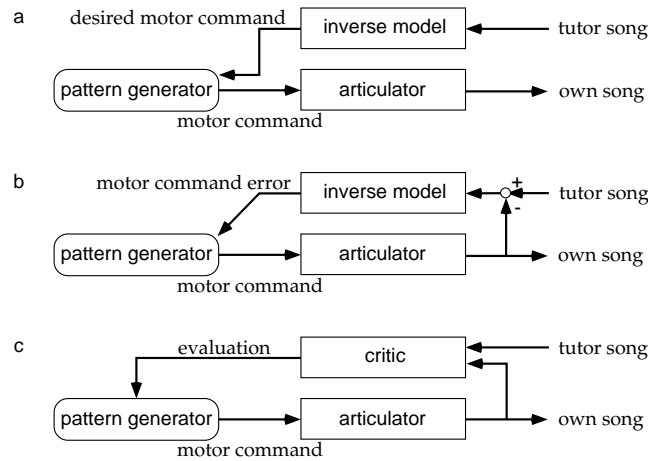

FIGURE 33.2 Different schemes for solving sensorimotor inverse problems. (a) One-shot learning by an inverse model of the motor system. (b) Error correction learning by an approxi-

mate inverse model. (c) Reinforcement learning by a stochastic controller and a critic.

Casland, 1987; Williams and Vicario, 1993; Vu, Kuo, and Chance, 1995). In a recent microstimulation experiment on singing birds, stimulation of HVc produced disruption of the sequence of syllables, whereas stimulation of RA only disrupted the pattern of individual syllables (Vu, Mazurek, and Kuo, 1994). Furthermore, recent study of extracellular recording from singing birds revealed that the activity patterns in HVc are uniquely associated with syllable identity, while precisely timed burst activities in RA are uniquely associated with subsyllabic components (A. C. Yu and Margoliash, 1996). These data suggest that HVc is a candidate site for representing sequences of syllables and that RA is a possible site where the motor patterns for each syllable are stored.

The indirect pathway consists of area X, DLM, and LMAN, forming a bypass from HVc to RA. This pathway is not directly involved in song production because lesions in this pathway in adult birds do not impair their “crystallized” songs (Nottebohm, Stokes, and Leonard, 1976). However, if a lesion is made at any point along the indirect pathway in young birds before the end of vocal learning, their songs become highly abnormal (Bottjer, Miesner, and Arnold, 1984; Sohrabji, Nordeen, and Nordeen, 1990; Scharff and Nottebohm, 1991). There have been a variety of hypotheses for the function of this pathway: comparison of sensory and motor representations of song (Williams, 1989), reinforcement of syllable specific activation patterns within RA (Bottjer et al., 1989), processing of auditory feedback and modulation of plasticity (Scharff and Nottebohm, 1991), a measure of how well a vocalization matches a particular auditory template (Doupe and Konishi, 1991), and selective reinforcement of synaptic connections from HVc to RA (Mooney, 1992).

FUNCTIONS FOR COMPONENTS OF THE SONG CONTROL SYSTEM We propose a functional model of the song control system based on the following experimental evidence:

1. Sequences of syllables are produced at the level of HVc (Vu, Mazurek, and Kuo, 1994; A. C. Yu and Margoliash, 1996).
2. RA is a myotopically organized (Vicario, 1991b).
3. Both the direct and indirect pathways linking HVc and RA are unidirectional (Bottjer et al., 1989).

These facts imply the following constraints on the localization of the computational processes suggested in the preceding list:

1. The representation of syllables suitable for auditory recognition and sequential memory is constructed in the ascending auditory pathway up to the level of HVc.
2. The memory and production of syllable sequences are performed within HVc.
3. The syllable representation in HVc needs to be transformed into muscle-oriented representation in RA.

Figure 33.3 illustrates our current working hypothesis about the functions of song-related nuclei. The ascending auditory pathway from the cochlea through the auditory thalamus and the forebrain auditory nucleus field L to HVc performs hierarchical processing of auditory input, leading to some internal representation of syllables that is useful for recognition and memory. On one hand, it is known that field L has a tonotopical organization (Bonke, Scheich, and Langner, 1979) and that the neurons respond to pure tone or band-limited noises (Margoliash, 1986). On the other hand, no tonotopical organization is found in HVc, whose neurons have more

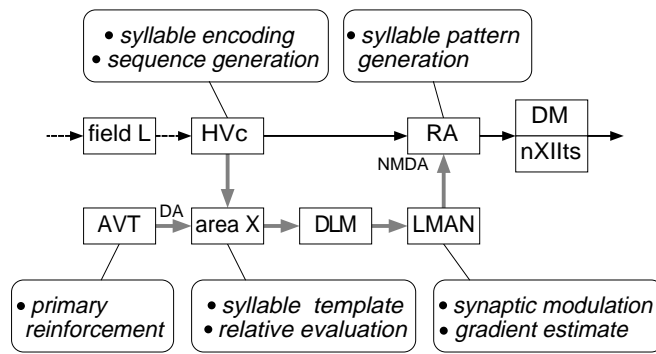

FIGURE 33.3 Schematic diagram indicating the proposed functions for each of the major nuclei of the song system. The direct pathway is shown at the top, starting with auditory input into field L. The anterior forebrain pathway starts at HVC and

makes a side loop to RA through area X and LMAN. The bullets in each balloon give the proposed function of the corresponding nucleus. See text for more details.

selective response properties to complex acoustic features, such as frequency modulation, combination of harmonics, sequence of notes, and sequence of syllables (Margoliash, 1983; Margoliash and Fortune, 1992; Lewicki and Konishi, 1995; Lewicki, 1996). Many cells are strongly tuned to the bird's own song (Margoliash, 1986). It has recently been found that the auditory responses of HVC neurons to different syllables have distributed and overlapping spatial patterns (Sutter and Margoliash, 1994), but the functional implication of such a representation remains to be studied.

HVC is regarded as the main center for memory and generation of syllable sequence (Vu, Mazurek, and Kuo, 1994; A. C. Yu and Margoliash, 1996). Sequence production in HVC is probably controlled by timing cues from NIf and Uva (McCasland, 1987; Williams and Vicario, 1993). Neurons in HVC show both auditory and motor responses (McCasland and Konishi, 1981; McCasland, 1987), but neither tonotopical or myotopical organization is seen in HVC. Nor has any simple correlation been reported between the auditory and motor responses for the same syllable (McCasland and Konishi, 1981; McCasland, 1987; C.-H. Yu and Margoliash, 1993). There appears to be a drastic change in the operation of HVC during singing: The spontaneous activity increases (C.-H. Yu and Margoliash, 1993; A. C. Yu and Margoliash, 1996), and the auditory response is suppressed for a few seconds afterward (McCasland and Konishi, 1981).

RA has topographic connection to nXIIts, which topographically projects to the muscles in the syrinx (Vicario, 1988; Vicario, 1991b). The dorsal part of RA projects to DM, which projects to the respiratory control system. Since no myotopical organization is apparent in HVC, the syllable representation in HVC would have to be transformed into a more muscle-oriented representation in the connection from HVC to RA. The anterior

forebrain pathway forms a side path to this motor decoding pathway. Lesions in area X or LMAN in adults do not affect crystallized songs, but disrupt song learning in young birds (Bottjer, Miesner, and Arnold, 1984; Sohrabji, Nordeen, and Nordeen, 1990; Scharff and Nottebohm, 1991). Neurons in area X, DLM, and LMAN have highly selective response to the bird's own song in adult birds (Doupe and Konishi, 1991), but some of them are selective to the tutor song in young birds (Solis and Doupe, 1995). Synaptic connections from LMAN to RA are formed prior to those from HVC (Konishi and Akutagawa, 1985) and are mediated mainly by NMDA-type glutamate receptors (Kubota and Saito, 1991; Mooney and Konishi, 1991), which are involved in development and learning in the mammalian central nervous system (Malenka and Nicoll, 1993; Fox and Zahs, 1994). These facts suggest that the function of the anterior forebrain pathway is to set up appropriate synaptic connections from HVC to RA that lead to a better match between the bird's own vocalization and the song template (Bottjer et al., 1989; Mooney, 1992; Doupe and Konishi, 1991; Doupe, 1993).

Based on these previous suggestions, we hypothesize that the anterior forebrain pathway functions to be a specific reinforcement learning system called an *adaptive critic*, as shown in figure 33.4 (Barto, Sutton, and Anderson, 1983). In a reinforcement learning paradigm, a stochastic perturbation is given to the motor commands, and if it results in better performance, the perturbed motor command is reinforced; that is, the perturbation is made permanent. In order for this learning scheme to work efficiently, it is necessary that the positive and negative reinforcement be balanced. An important role of the critic is to evaluate the present performance relative to the recent average performance, a method known as *reinforcement comparison* (Sutton and Barto, 1998). In the context of syllable vocalization learning, we propose that

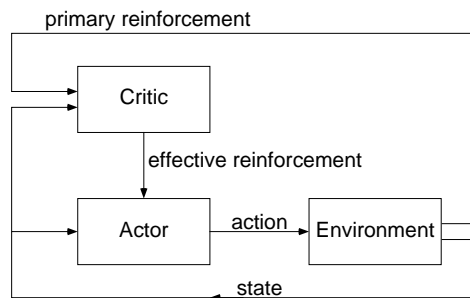

FIGURE 33.4 A block diagram showing the actor-critic architecture for a feedback control task (Barto, Sutton, and Anderson, 1983). The direct control pathway is the closed loop between the actor and the environment. The control policy is learned through interaction with the critic, which evaluates the sensory feedback caused by the action of the actor. A scalar reinforcement signal generated by the critic is used by the actor to modify its future action. The critic receives information used for the evaluation from a primary reinforcer. In the birdsong literature, the term “template” is used for the information used by the critic to perform the evaluation.

LMAN provides stochastic perturbation to the HVC-to-RA connection and that area X evaluates how well the resulting syllable matches the template. The raw similarity index is compared to the recent average similarity index for the syllable, and the relative evaluation signal then determines whether the temporary change in the HVC-to-RA connection is made permanent or not. In this scheme, the evaluation and perturbation modules are on a side path to the main motor control pathway and are not necessary for control when learning is completed.

Several lines of evidence support this hypothesis. Lesions in area X and LMAN in young birds result in contrasting deficits (Scharff and Nottebohm, 1991). Early area X lesion results in unstable singing in the adulthood when songs are normally crystallized. This effect is similar to that of early deafening. Early lesion in LMAN results in stable but poorly structured song with fewer syllables than normal. These observations are nicely explained if we assume that area X serves as the critic, which provides evaluation of vocalization based on auditory feedback, and that LMAN modulates the connection strengths from HVC to RA and provides a random element to the controller.

The hypothesis that area X functions as a critic is supported by the fact that it receives dopaminergic input from a midbrain nucleus AVT, the avian homologue of mammalian ventral tegmental area (Lewis et al., 1981; Casto and Ball, 1994). Activity of the dopamine system is related to reward in many species (Schultz, Apicella, and Ljungberg, 1993). During auditory learning, this dopaminergic input can be used for selection of auditory input that is to be memorized as song template. It has been shown that a young bird does not indiscriminately

memorize all of its auditory experience as its song template. When a young zebra finch is caged with several adult birds, it selects most of its song syllables from the adult that had most frequent interaction with the bird, especially feeding interactions (Williams, 1990). We postulate that this selection of auditory input that is to be memorized as song template happens in area X by association of auditory input from HVC and reward input from AVT. In other words, whereas the auditory tuning of HVC cells should simply reflect auditory experience, responses of area X cells are tuned to the specific songs to be learned. Although the majority of neurons in both HVC and area X in young birds are tuned to the bird’s own developing song rather than to the tutor song (Volman, 1993; Doupe, 1993), some of the neurons in area X have preferred tuning to the tutor song (Solis and Doupe, 1995). During the sensorimotor learning phase, the activation level of those neurons could be used to evaluate the match between the vocalization of the bird and that of the tutor. Furthermore, if the function of area X is not simply to detect a match to the stored template but also to provide “relative” evaluation based on recent level of performance, then there should be many cells that are tuned more to the bird’s current song than to the tutor song.

As mentioned earlier, synaptic input from LMAN to RA is predominantly mediated by NMDA-type glutamate receptors, whereas input from HVC to RA is mainly mediated by non-NMDA-type receptors (Kubota and Saito, 1991; Mooney and Konishi, 1991). The NMDA-type input from LMAN may enable both short-term and long-term changes in the HVC-to-RA synaptic efficacy during sensorimotor learning. It has been observed in slice preparations that simultaneous stimulation of both HVC and fibers originating in LMAN results in a response larger than the linear summation of individual responses (Mooney, 1992), consistent with some nonlinear interaction between these two inputs. For example, when there is a tonic NMDA-type input, the postsynaptic response to the same non-NMDA-type input is amplified, which effectively modulates the synaptic conductance of the non-NMDA inputs (Thomson and Deuchars, 1994). Although long-term changes of synaptic strengths have not yet been found in RA, activation of NMDA-type receptors triggers plastic synaptic change in many other central nervous systems (Malenka and Nicoll, 1993).

Computer simulations of vocalization learning

We focus on only one of the three computational problems in song learning, namely that of finding the motor commands needed to produce a desired auditory

FIGURE 33.5 The model of the syrninx used in the song learning model. The sound output was controlled by four input variables: A , gain of the amplifier; F , fundamental frequency of the sound source; P , peak frequency; and S , sharpness of the band-pass filter. In addition to these parameters, the output was governed by units with a range of temporal responses (see figure 33.6).

impression. The question we asked is whether the reinforcement learning scheme that we have outlined can be implemented within the known biological constraints and whether such a system can perform sensorimotor learning within a realistic number of trials. We required the model to produce sound that could be compared to real birdsong.

The outline of the simulation system is as follows. We built a simple model of the syrninx, the avian vocal organ, and then constructed a neural network model of RA and HVc that sends a series of motor commands to the syrninx model. We implemented the adaptive critic learning system by assigning the stochastic perturbation to LMAN and the syllable evaluation to area X. Since it was beyond the scope of the present investigation to model the detailed mechanisms of auditory encoding and sequential memory, we used simplified spectrographic template matching for syllable templates and unary encoding of syllables in HVc, which are not necessarily biologically realistic.

SYRNIX: SOUND SYNTHESIZER In order to test the performance of the model of the vocal control system, we designed a computer program that mimics the function of the syrninx, the avian vocal organ located near the junction of the trachea and the bronchi (Brackenbury, 1982; Vicario, 1991a). The sound source for the syrninx is the oscillation of a pair of tympaniform membranes on the medial side of the bronchi. Depending on the tension of the membrane and the airflow around it, which are controlled by the activity of six pairs of syringeal muscles, the syrninx can produce pure tones, harmonic sounds, and nonharmonic sounds with complex frequency modulation (Casey and Gaunt, 1985). Activation of the dorsal syringeal muscles coincides with the air flow in the bronchus, and activation of the ventral syringeal muscles correlates well with the fundamental oscillation frequency of the sound (Goller and Suthers, 1995). The

spectral profile of the sound is also affected by the resonance property of the vocal tract (Nowicki, 1987).

A simple model of the syrninx, shown in figure 33.5, consisted of a variable-frequency sound source, a band-pass filter, and an amplifier. A triangular wave form was used for the sound source because it includes all the integer harmonic components. The output of this sound synthesizer was controlled by the following four variables: the fundamental frequency of the harmonic sound source F , the peak frequency P , the sharpness S of the band-pass filter, and the gain of the amplifier A . The output sound waveform $x(t)$ was calculated from the time course of the variables ($A(t), F(t), P(t), S(t)$), which had values between zero and one:

$$\begin{aligned}\dot{\phi}(t) & f_0 \, 1 \, (f_1 - f_0) F(t) \\ z(t) & [\phi(t) \bmod 1] \, 3 \, 2 - 1 \\ \omega(t) & 2\pi [f_2 \, 1 \, (f_3 - f_2) P(t)] \\ \mu(t) & \mu_0 \, 1 \, (\mu_1 - \mu_0) S(t) \\ \dot{u}(t) & \omega(t) [z(t) - u(t)] - \mu v(t) \\ \dot{v}(t) & \mu u(t) - \omega(t) v(t) \\ x(t) & A(t) u(t)\end{aligned}$$

where $\phi(t)$ and $z(t)$ are the phase and the output of the harmonic oscillator, and $\omega(t)$ and $\mu(t)$ are the angular frequency and damping factor of the band-pass filter, respectively. The values of the parameters were $f_0 = 0.4$ kHz, $f_1 = 1.2$ kHz, $f_2 = 2$ kHz, $f_3 = 8$ kHz, $\mu_0 = 1.0 \text{ ms}^{-1}$, and $\mu_1 = 0.1 \text{ ms}^{-1}$. The system was numerically integrated by the Euler method using a time step of $1/32$ ms. The model could produce “birdlike” chirps and warbles with the time courses of the input variables chosen appropriately (figure 33.9).

RA: SYLLABLE PATTERN GENERATOR RA is capable of producing a variety of temporal responses in order to produce command outputs for syllables with various spectral features. Several constraints are available from experimental studies. First, RA has a myotopical organization (Vicario, 1991b). Second, in slice preparations, HVc input to RA evokes fast non-NMDA-type, slower NMDA-type, and delayed polysynaptic inhibitory responses (Mooney, 1992). Third, neurotransmitters mediated by second-messenger systems such as norepinephrine and GABA_B agonists also have effects on neurons in RA on slower time scales (Perkel, 1994). Although the details of the local circuits in RA are not yet known, the observed cellular and synaptic time courses could produce the complex temporal responses needed to produce syllables in response to command inputs from HVc.

To mimic myotopical organization, the model of RA had four subnetworks, each of which could exert control

FIGURE 33.6 Model of the direct motor pathway. Syllables were unary coded in HVC, and their sequential activation triggered syllable pattern generation networks in RA. The RA units were divided into four groups corresponding to the four motor command variables (A , F , P , S). Within each group, there were k exponential temporal kernels with different time constants. The sum of their response profiles served as the motor command for the syrinx model.

on one of the four output motor command variables (A , F , P , S). Within each subnetwork, there were $k = 5$ “temporal response kernels,” where each unit had a different time course, as shown in figure 33.6. The temporal response of an RA unit $r_j(t)$ to the input from HVC $s_i(t)$ ($i = 1, \dots, n$) was

$$\begin{aligned} p_j(t) &= \sum_i w_{ji} s_i(t) \\ \tau_j \dot{q}_j(t) &= p_j(t) - q_j(t) \\ r_j(t) &= p_j(t) - q_j(t) \end{aligned}$$

where $p_j(t)$ is the input sum, $q_j(t)$ is delayed inhibition or adaptation, and τ_j is the time constant of the j th unit. The motor command output was synthesized from a combination of these responses:

$$m^C(t) = f \left[\sum_j r_j^C(t) + 1 + b^C \right]$$

where index C denotes one of the command variables (A , F , P , S), f is a sigmoid function $f(x) = 1/[1 + \exp(-4x)]$, and b is the bias. The time constants of the $k = 5$ kernels were $\tau_1 = \infty$ [i.e., $r_j(t) = p_j(t)$], $\tau_2 = 80$, $\tau_3 =$

40, $\tau_4 = 20$, and $\tau_1 = 10$ (ms). In order to assure clear syllable onset and offset, the bias for the sound amplitude was $b^A = -1$, and the weight for the first kernel was initially set as $w_{1i}^A = 1$. Other biases and initial weights were set to zero. The weights w_{ji} were initialized at the beginning of learning to random values generated with a Gaussian distribution having a standard deviation of 0.1. The reinforcement learning algorithm given in the next subsection incrementally changed the weights corresponding to each syllable.

HVC: SEQUENCE GENERATOR In recordings from HVC in awake birds, some neurons became activated preceding specific syllables (McCasland, 1987; A. C. Yu and Margoliash, 1996). A simple syllable coding was adopted in which all the neurons that become active for the i th syllable were aggregated as the state of a single “unit,” s_i . The onset and offset of each syllable in a tutor song was detected by thresholding the sound amplitude and storing the interval in an event table. During the course of a song, each syllable coding unit s_i , was turned on ($s_i = 1$) and off ($s_i = 0$) at the stored onset and offset time. This “unary encoding” scheme is oversimplified, and there is evidence that the motor encoding of syllables has overlaps, so that a single HVC unit would be active during more than one syllable (A. C. Yu and Margoliash, 1996), as in the case of auditory encoding (Sutter and Margoliash, 1994). A distributed encoding could have been used to model HVC, but this was not included in the present model for simplicity.

LMAN: STOCHASTIC GRADIENT ASCENT The vocal output is determined by the connection weight matrix $W = \{w_{ji}^A, w_{ji}^F, w_{ji}^P, w_{ji}^S\}$ based on the preceding models of HVC, RA, and the syrinx. The goal of motor learning then is to find a point in this $4kn$ -dimensional weight space that produces a vocalization that maximizes the evaluation of the template-matching measure. In the reinforcement learning algorithm used here, this goal was accomplished by a stochastic method for optimizing the evaluation function.

In the first step of the learning algorithm, the output motor command from RA was stochastically perturbed by temporarily changing the input connection strengths from HVC. Such perturbations in the output of RA units could be produced by the modulation of the HVC-to-RA connection weights by NMDA-type synaptic input from LMAN. The perturbation of the weights was implemented as a static weight change δw_{ji} during each song trial. This produces a perturbation in the RA:

$$\delta p_j(t) = \sum_i \delta w_{ji} s_i(t)$$

The second step was to evaluate this perturbed song by comparing it with the song template. By the procedure mentioned in the next section (on area X), a syllable-specific value \hat{r} , the “effective” reinforcement, was derived. Finally, the weights were permanently changed based on correlations among the inputs, outputs, and the evaluation (Barto and Jordan, 1987; Barto, 1995):

$$\Delta w_{ji} \propto \hat{r} \times \delta p_j(t) \times s_i(t)$$

With the unary encoding scheme of HVC adopted here, this expression reduces to

$$\Delta w_{ji} \propto \hat{r} \times \delta w_{ji}$$

since only one syllable unit i is active ($s_i = 1$). In other words, the temporary synaptic modulation δw_{ji} persists as a plastic change Δw_{ji} if the effective evaluation is positive, which is a kind of “weight perturbation” optimization algorithm (Alspector et al., 1993; Unnikrishnan and Venugopal, 1994).

A refinement of this basic reinforcement algorithm was used that improved the convergence of the learning. For each trial T , the temporary weight perturbation $\delta w_{ji}(T)$ was the sum of the evaluation gradient estimate $G_{ji}(T)$ defined subsequently and a random perturbation $N_{ji}(T)$ of size η :

$$\delta w_{ji}(T) = G_{ji}(T) + \eta N_{ji}(T)$$

The network with perturbed weights $w_{ji}(T) + \delta w_{ji}(T)$ was used to produce a vocal output, and its evaluation $\hat{r}(T)$ was given by the model of area X described in the next subsection. The weights were then permanently changed only if the trial was successful:

$$w_{ji}(T+1) = w_{ji}(T) + \delta w_{ji}(T) \quad \text{if } \hat{r}(T) > 0$$

The estimate of gradient in the weight space $G_{ji}(T)$ was updated by the sum of the perturbations $\delta w_{ji}(T)$ multiplied by the effective evaluation:

$$G_{ji}(T) = \alpha \hat{r}(T) \delta w_{ji}(T) + (1 - \alpha) G_{ji}(T)$$

where the constant $0 < \alpha < 1$ controls the influence of the new trial on the running average over trials. A geometrical interpretation of this learning algorithm is illustrated in figure 33.7. The weighted running average of the weight change is like the “momentum” that is commonly used in other neural network learning algorithms (Rumelhart, Hinton, and Williams, 1986). We used $\alpha = 0.2$ and $\eta = 0.02$ in all the simulations reported here.

AREA X: EVALUATION BY SPECTROGRAPHIC TEMPLATE MATCHING The activation levels of the neurons selective for the tutor song that have been observed in area X

FIGURE 33.7 Estimate of evaluation gradient G from weighted summation of perturbation vectors. The vertical axis is the evaluation \hat{r} , and each point in the W plane represents a choice for two of the weights (there were many more in the actual model). The gradient G (central arrow) gives the running average of the evaluation function over the recent history of stochastically chosen weights, represented by the thin vectors from the central thick arrow.

(Solis and Doupe, 1995) could represent the similarity of the recently produced syllable to the corresponding tutor syllable (Doupe and Konishi, 1991). The evaluation of each syllable was assumed to be available separately, and a simple spectrographic template-matching method was used for evaluating its similarity to the tutor syllable, as follows.

First, the sound waveform from the bird was transformed into a spectrogram, which had 80 frequency channels in steps of 100 Hz, sampled every 1 ms. The onset and offset of the syllable were detected by appropriately setting a threshold for the sound amplitude. The spectrographic pattern of each syllable was down-sampled with a Gaussian filter having 40 frequency bins and 20 temporal bins, to accommodate slight variations in both frequency and time domains. The resulting 800-dimensional vector was normalized and then stored as the template vector for each syllable. A sample vector for a synthesized syllable was made in the same way. The correlation $0 \leq r \leq 1$ between the template and sample vector was used as the raw evaluation score.

We further assumed that area X functions as an “adaptive” critic that provides the evaluation in a form relative to currently expected level of performance. The running average \bar{r} of the evaluation r was updated at each time step:

$$\bar{r}(T+1) = \beta r(T) + (1 - \beta) \bar{r}(T)$$

where $0 < \beta < 1$ is the smoothing constant for the averaging. The “effective evaluation” \hat{r} that was used for learning in LMAN was given by

$$\hat{r}(T) = \tanh\{[r(T) - \bar{r}(T)]/\gamma\}$$

The squashing function \tanh was used to regulate the learning process. We used $\beta = 0.1$ and $\gamma = 0.1$ in all simulations.

ZEBRA FINCH SONG SAMPLES Songs of male adult zebra finches were recorded and digitized at 12 bits and with a 32-kHz sampling rate by Michael Lewicki at the California Institute of Technology.

Computer simulation was performed on Sparc Station 10 (Sun Micro Systems) with an audio interface to facilitate evaluation of songs by human ears. The simulation system was programmed in the C language and took approximately 30 minutes to simulate 500 learning trials. The results reported in the next subsection were confirmed in at least five simulation runs using different random seeds for the stochastic learning.

LEARNING A ZEBRA FINCH SONG Figure 33.8 shows an example of how the song learning simulator performed. The spectrogram of a song motif of a zebra finch is displayed in the top row. Ten syllables in the motif were identified (shown in boxes), and their spectrographic patterns were stored as syllable templates. Ten
